Technical Report on C++ Performance (DRAFT)

Executive Summary:

The aim of this report is:

- to give the reader a model of time and space overheads implied by use of various C++ language and library features,
- to debunk widespread myths about performance problems,
- to present techniques for use of C++ in applications where performance matters, and
- to present techniques for implementing C++ language and standard library facilities to yield efficient code.

As far as run-time and space performance is concerned, if you can afford to use C for an application, you can afford to use C++ in a style that uses C++’s facilities appropriately for that application.

This report first discussed areas where performance issues matters, such as various forms of embedded systems programming and high-performance numerical computation. After that, the main body of the report considers the basic cost of using language and library facilities, techniques for writing efficient code, and the special needs of embedded systems programming.

Performance implications of object-oriented programming are presented. This discussion rests on measurements of key language facilities supporting OOP, such as classes, class member functions, class hierarchies, virtual functions, multiple
inheritance, and run-time type identification (RTTI). It is demonstrated that, with the exception of RTTI, current C++ implementations can match hand-written low-level code for equivalent tasks. Similarly, the performance implications of generic programming using templates are discussed. Here, however, the emphasis is on techniques for effective use. Error handling using exceptions is discussed based on another set of measurements. Both time and space overheads are discussed. In addition, the predictability of performance of a given operation is considered.

The performance implications of IOSTreams and locales are examined in some detail and many generally useful techniques for time and space optimisations are discussed here.

Finally, the special needs of embedded systems programming are presented, including ROMability and predictability. And appendices present general C and C++ interfaces to the basic hardware facilities of embedded systems.

1 Introduction

"Performance" has many aspects - execution speed, code size, data size, and memory footprint at run-time, or time and space consumed by the edit/compile/link process. It could even refer to the time necessary to find and fix code defects. Most people are primarily concerned with execution speed, although program footprint and memory usage can be critical for small embedded systems where the program is stored in ROM, or where ROM and RAM are combined on a single chip.

Efficiency has been a major design goal for C++ from its earliest days; also, the principle of "zero overhead" for any feature that is not used in a program. It has been a guiding principle from the earliest days of C++ that "you don't pay for what you don't use".

Language features that are never used in a program should not have a cost in extra code size, memory size, or run-time. If there are places where C++ cannot guarantee zero overheads for unused features, this paper will attempt to document them. It will also discuss ways in which compiler writers, library vendors, and programmers can minimize or eliminate performance penalties, and will discuss the trade-offs among different methods of implementation.

Programming for resource-constrained environments is another focus of this paper. Typically, it is very small or very large programs that run into resource limits of some kind. Very large programs, such as database servers, may run into limits of disk space or virtual memory. At the other extreme, an embedded application may be constrained to run in the ROM and RAM space provided by a single chip, perhaps a total of 64K of memory, or even smaller.

Apart from the issues of resource limits, some programs must interface with system hardware on a very low level. Historically the interfaces to hardware have been implemented as proprietary extensions to the compiler (often as macros). This led to the situation that code has not been portable, even for programs written for a given environment, because each compiler for that environment has implemented different sets of extensions.
1.1 Brief Glossary

**Cache** - a buffer of high-speed memory used to improve access times to medium-speed main memory or to low-speed storage devices. If an item is found in cache memory (a "cache hit"), access is faster than going to the underlying device. If an item is not found (a "cache miss"), then it must be fetched from the lower-speed device.

**Code Bloat** - the generation of excessive amounts of code instructions, as from unnecessary template instantiations.

**Code Size** - the portion of a program's memory image devoted to instructions. Sometimes immutable data is placed with the code.

**Data Size** - the portion of a program's memory image devoted to static data.

**Embedded System** - a program which functions as part of a device. Often the software is burned into firmware instead of loaded from a storage device. It usually is a free-standing implementation rather than a hosted one with an operating system.

**Locality of Reference** - the principle that most programs tend to make most accesses to locations near those accessed in the recent past. Keeping items accessed together in locations near each other increases cache hits and decreases page faults.

**Overlays** - another, older, technique for handling programs that are larger than available memory. Different parts of the program are arranged to share the same memory, with each overlay loaded on demand when another part of the program calls into it. The use of overlays has largely been succeed by virtual memory addressing where it is available, but it may still be used in memory-limited embedded environments or where precise programmer or compiler control of memory usage improves performance.

**Page** - a collection of memory addresses treated as a unit, for partitioning memory between applications or swapping out to disk.

**Page Fault** - an interrupt triggered by an attempt to access a virtual memory address not currently in physical memory, and thus the need to swap virtual memory from disk to hardware.

**Real-Time** - refers to a system in which average performance and throughput must meet defined goals, but some variation in performance of individual operations can be tolerated (also "Soft Real-Time"). "Hard Real-Time" means that every operation must meet specified timing constraints.

**System-on-Chip (SoC)** – a term referring to an embedded system where most of the functionality of the system is implemented on a single chip, including the processor(s), RAM and ROM.

**Text Size** – a common alternative name for “Code Size”.

Page 8 of 138
Virtual Memory Addressing - a technique for enabling a program to address more memory space than is physically available. Typically, portions of the memory space not currently being addressed by the processor can be "swapped out" to disk space. A mapping function, sometimes implemented in specialized hardware, translates program addresses into physical hardware addresses. When the processor needs to access an address not currently in physical memory, some of the data in physical memory is written out to disk and some of the stored memory read from disk into hardware memory. Since reading and writing to disk is slower than accessing memory chips, minimizing swaps leads to faster performance.

Working Set - the portion of a running program that is in physical memory, not swapped out, at any given time.

1.2 Typical Application Areas
Since no computer has infinite resources, all programs have some kind of limiting constraints. However, many programs never encounter these limits in practice. Very small and very large systems are those most likely to need effective management of limited resources.

1.2.1 Embedded Systems:
Embedded Systems have many restrictions on memory-size and timing requirements that are more significant than are typical for non-Embedded systems. Embedded Systems are used in various applications areas as follows¹:

- Scale:
  - small
    - These systems typically use single chips containing both ROM and RAM. Single-chip systems (System-on-Chip or SoC) in this category typically hold approximately 32KBytes for RAM and 32, 48 or 64KBytes for ROM².
    - Examples of applications in this category are:
      - Engine control for automobiles
      - Hard disk controllers
      - Consumer electronic appliances
      - Smart cards, also called Integrated Chip (IC) cards – about the size of a credit card; they usually contain a processor system with code and data embedded in a chip which is embedded (in the literal meaning of the word) in a plastic card. A typical size is 4KBytes of RAM, 96KBytes of ROM and 32KBytes EEPROM. An even more constrained smart card In use

¹ Typical systems during the Year 2001
² These numbers are derived from the popular C8051 chipset.
contains 12KBytes or ROM, 4KBytes of flash memory and only 600Bytes of RAM data storage.

- **medium**
  
  These systems typically use separate ROM and RAM chips to execute a fixed application, where size is limited. There are different kinds of memory chip, and systems in this category are typically composed of several kinds to achieve different objectives for cost and speed. Examples of applications in this category are:
  
  - Hand-held digital VCR
  - Printer
  - Copy machine
  - Digital still camera – one common model uses 32MBytes of flash memory to hold pictures, plus faster buffer memory for temporary image capture, and a processor for on-the-fly image compression.

- **large**
  
  These systems typically use separate ROM and RAM chips, where the application is flexible and the size is relatively unlimited. Examples of applications in this category are:
  
  - Personal Digital Assistant (PDA) – equivalent to a personal computer without a screen, keyboard, or hard disk.
  - Digital television
  - Set-top box
  - Car navigation system
  - Central controllers for large production lines of manufacturing machines

- **Timing:**
  
  Of course, systems with real-time or hard real-time constraints are not necessarily embedded systems; they may run on hosted environments.

- **Critical (real-time and hard real-time systems)**
  
  Examples of applications in this category are:
  
  - Motor control
  - Hand-held digital VCR
  - Mobile phone
  - CD or DVD player
  - Electronic musical instruments
  - Hard disk controllers
  - Digital television
  - Digital Signal Processing (DSP) applications
o Non-critical

Examples of applications in this category are:

- Digital still camera
- Copy machine
- Printer
- Car navigation system

1.2.2 Servers:

For server applications, the performance-critical resources are typically speed (e.g. transactions per second), and working-set size (which also impacts throughput and speed). In such systems, memory and data storage are expressed in terms of megabytes or even gigabytes.

Often there are soft real-time constraints, bounded by the need to provide service to many clients in a timely fashion. Some examples of such applications include the central computer of a public lottery where transactions are heavy, or large scale high-performance numerical applications, such as weather forecasting, where the calculation must be completed within a certain time.

These systems are often described in terms of dozens or even hundreds of multiprocessors, and the prime limiting factor may be the Mean Time Between Failure (MTBF) of the hardware (increasing the amount of hardware results in a decrease of the MTBF – in such a case, high-efficiency code would result in greater robustness).
2 Overheads of C++ Features

Does the C++ language have inherent complexities and overheads, which make it unsuitable for performance-critical applications? For a program written in the C-conforming subset of C++, will penalties in code size or execution speed result from using a C++ compiler instead of a C compiler? Does C++ code necessarily result in "unexpected" functions being called at run-time, or are certain language features, like multiple inheritance or templates, just too expensive (in size or speed) to risk using? Do these features impose overheads even if they are not explicitly used?

This paper examines the major features of the C++ language that are perceived to have an associated cost, whether real or not:

- Namespaces
- Type Conversion Operators
- Inheritance
- Run-Time Type Information (RTTI)
- Exception Handling (EH)
- Templates
- The Standard I/OStreams Library

2.1 Namespaces

Namespaces do not add any space or time overheads to code. They do, however, add some complexity to the rules for name lookup. The principal advantage of namespaces is that they provide a mechanism for partitioning names in large projects in order to avoid name clashes.

Namespace qualifiers enable programmers to use shorter identifier names when compared with alternative mechanisms. In the absence of namespaces, the programmer has to explicitly alter the names to ensure that name clashes do not occur. One common approach to this is to use a canonical prefix on each name:

```c
static char* mylib_name = "My Really Useful Library";
static char* mylib_copyright = "June 15, 2001";
```

Another common approach is to place the names inside a `class` and use them in qualified form:

```c
class ThisLibInfo {
    static char* name;
    static char* copyright;
};

char* ThisLibInfo::name = "Another Useful Library";
char* ThisLibInfo::copyright = "December 18, 2001";
```

With namespaces, the number of characters necessary is similar to the `class` alternative, but unlike the `class` alternative, qualification can be avoided with using declarations, which move the unqualified names into the current scope, thus allowing
the names to be referenced by their shorter form. This saves the programmer from having to type those extra characters in the source program.

2.2 Type Conversion Operators
C and C++ permit explicit type conversion using cast notation (§IS-5.4), for example:

```c
int i = (int)3.14159;
```

Standard C++ adds four additional type conversion operators, using syntax that looks like function-template, for example:

```c
int i = static_cast<int> ( 3.14159 );
```

The four syntactic forms are:

- `const_cast<Type>(expression)`  // §IS-5.2.11
- `static_cast<Type>(expression)` // §IS-5.2.9
- `reinterpret_cast<Type>(expression)`  // §IS-5.2.10
- `dynamic_cast<Type>(expression)`  // §IS-5.2.7

The semantics of cast notation (which is still recognized) are the same as the type conversion operators, but distinguish between the different purposes for which the cast is being used. The type conversion operator syntax is easier to identify in source code, and thus contributes to writing programs that are more likely to be correct³. It should be noted that as in C, a cast may create a temporary object of the desired type, so casting can have run-time implications.

The first three forms of type conversion operator have no size or speed penalty versus the equivalent cast notation. Indeed, it is typical for a compiler to transform cast notation into one of the other type conversion operators when generating object code. However, `dynamic_cast<T>` may incur some overhead at run-time if the required conversion involves using RTTI mechanisms such as cross-casting (§2.3.8).

2.3 Classes and Inheritance
Programming in the object-oriented style often involves heavy use of class hierarchies. This section examines the time and space overheads imposed by the primitive operations using classes and class hierarchies. Often, the alternative to using class hierarchies is to perform similar operations using lower-level facilities. For example, the obvious alternative to a virtual function call is an indirect function call. For this reason, the cost of primitive operations of classes and class hierarchies are compared to similar functionality implemented without classes.

Most comments about run-time costs are based on a set of simple measurements performed on three different machine architectures using six different compilers run with a variety of optimisation options. Each test was run multiple times to ensure that the results were repeatable. The code used is presented in Appendix E:. The aim of these measurements is neither to get a precise statement of optimal performance of

---
³ If the compiler does not provide the type conversion operators natively, it is possible to implement them using function-templates. Indeed, prototype implementations of the type conversion operators were often implemented this way.
C++ on a given machine nor to provide a comparison between compilers or machine architectures. Rather, the aim is to give developers a view of relative costs on common language constructs using current compilers, and also to show what is possible (what is achieved in one compiler is in principle, possible for all). We know – from specialized compilers not in this study and reports from people using unreleased beta versions of popular compilers – that better results are possible.

In general, the statements about implementation techniques and performance are believed to be true for the vast majority of current implementations, but are not meant to cover experimental implementation techniques, which might produce better – or just different – results.

2.3.1 Representation Overheads

A class without a virtual function requires exactly as much space to represent as a struct with the same data members. That is, no space overhead is introduced from using a class compared to a C struct. A class object does not contain any data that the programmer didn’t explicitly request. In particular, a non-virtual function does not take up any space in an object of its class. Similarly, a static member takes up no space in an object.

A class that has one or more virtual functions incurs a space overhead of one pointer per object plus a “virtual function table” of one to two words per virtual function plus a “type information” object with a size in the order of a couple of words + a name string + a couple of words per base-class. This latter “type information” (also called “run-time type information” or RTTI) is typically about 40 bytes per class. Whole program analysis (WPA) can be used to eliminate unused virtual function tables and RTTI data. Such analysis is particularly suitable for relatively small programs that do not use dynamic linking, and which have to operate in a resource-constrained environment such as an embedded system.

Some current C++ implementations share data structures between RTTI support and exception handling support, thereby avoiding representation overhead specifically for RTTI.

Aggregating data items into a class or struct can impose a run-time overhead if a compiler doesn’t effectively use registers or in other ways fail to take advantage of possible optimisations when class objects are used. The overheads incurred through the failure to optimise in such cases are referred to as “the abstraction penalty” and are usually measured by a benchmark produced by Alex Stepanov. For example, if accessing a value through a trivial smart pointer is significantly slower than accessing it through an ordinary pointer, the compiler is inefficiently handling the abstraction. In the past, most compilers had significant abstraction penalties and several current compilers still do. However, at least two compilers\(^4\) have been reported to have abstraction penalties below 1% and another a penalty of 3% so eliminating this kind of overhead is well within the state of the art.

\(^4\) These are production compilers, not just experimental ones.
2.3.2 Basic Class Operations
Calling a non-virtual, non-static, non-inline member function of a class costs as much as calling a freestanding function with one extra pointer argument indication the data on which the function should operate. Consider a set of simple runs of the test program described in Appendix E:

<table>
<thead>
<tr>
<th>Table 2.3-1</th>
<th>#1</th>
<th>#2</th>
<th>#3</th>
<th>#4</th>
<th>#5</th>
</tr>
</thead>
<tbody>
<tr>
<td>non-virtual:</td>
<td>px-&gt;f(l)</td>
<td>0.019</td>
<td>0.002</td>
<td>0.016</td>
<td>0.085</td>
</tr>
<tr>
<td></td>
<td>g(ps,l)</td>
<td>0.020</td>
<td>0.002</td>
<td>0.016</td>
<td>0.067</td>
</tr>
<tr>
<td>non-virtual:</td>
<td>x.g(l)</td>
<td>0.019</td>
<td>0.002</td>
<td>0.016</td>
<td>0.085</td>
</tr>
<tr>
<td></td>
<td>g(&amp;s,l)</td>
<td>0.019</td>
<td>0</td>
<td>0.016</td>
<td>0.067</td>
</tr>
<tr>
<td>static member: X::h(l)</td>
<td>0.014</td>
<td>0</td>
<td>0.013</td>
<td>0.069</td>
<td>0</td>
</tr>
<tr>
<td>h(l)</td>
<td>0.014</td>
<td>0</td>
<td>0.013</td>
<td>0.071</td>
<td>0.001</td>
</tr>
</tbody>
</table>

The compiler/machine combinations #1 and #2 match “naïve expectations” exactly, by having calls of a member function exactly match calls of a non-member function with an extra pointer argument. As expected, the two last calls (the X::h(l) call of a static member function and the h(l) call of a global function) are faster because they don’t pass a pointer argument. Implementations #3 and #5 demonstrates that a clever optimiser can take advantage of implicit inlining and (probably) caching to produce results for repeated calls that are 10 times (or more) faster than what is achievable if a function call is generated. Implementation #4 shows a small (<15%) advantage to non-member function calls over member function calls, which (curiously) is reversed when no pointer argument is passed. Implementations #1, #2, and #3 were run on one system, while #4 and #5 were run on another.

The main lesson drawn from this table is that any differences that there may be between non-virtual function calls and non-member functions calls are minor and far less important than differences between compilers/optimisers.

2.3.3 Virtual Functions
Calling a virtual function is roughly equivalent to calling a function through a pointer stored in an array:

<table>
<thead>
<tr>
<th>Table 2.3-2</th>
<th>#1</th>
<th>#2</th>
<th>#3</th>
<th>#4</th>
<th>#5</th>
</tr>
</thead>
<tbody>
<tr>
<td>virtual:</td>
<td>px-&gt;f(l)</td>
<td>0.025</td>
<td>0.012</td>
<td>0.019</td>
<td>0.078</td>
</tr>
<tr>
<td></td>
<td>p<a href="ps,l">1</a></td>
<td>0.020</td>
<td>0.002</td>
<td>0.016</td>
<td>0.055</td>
</tr>
<tr>
<td>virtual:</td>
<td>x.f(l)</td>
<td>0.020</td>
<td>0.002</td>
<td>0.016</td>
<td>0.071</td>
</tr>
<tr>
<td></td>
<td>p<a href="&amp;s,l">1</a></td>
<td>0.017</td>
<td>0.013</td>
<td>0.018</td>
<td>0.055</td>
</tr>
</tbody>
</table>
Here it is the compiler/machine combination #3 that most closely matches the naïve model of what is going on. The cost of virtual and pointer to function calls is identical (when averaged over a few runs, the minor difference seen above averages out) except for \( x.f(1) \) where implementations #2 and #5 notice that the virtual function table need not be used because the exact type of the object is known and a non-virtual call can be used. This simple and useful optimisation was present in Cfront 1.1 (1986)\(^5\) [MartinO: Actually, this claim is not true. I tried it out using the Glockenspiel versions of Cfront 1.1 and 1.2, and this optimisation does not take place] and it is a bit sad to see that it can’t be taken for granted in 2001. Implementations #4 and #5 appear to have systematic overheads for virtual function calls (caused by treating single-inheritance and multiple-inheritance equivalently, and thus missing an optimisation). However, this overhead is in the order of 20% and 12% - far less than the variability between compilers.

Comparing Table 2.3-1 and Table 2.3-2, we see that implementations #1, #2, #3, and #5 confirms the obvious assumption that virtual calls (and indirect calls) are more expensive than non-virtual calls (and direct calls). Interestingly, the overhead are in the range 20% to 25% where one would expect it to be, based on a simple count of operations performed. However, implementations #2 and #5 demonstrate how (implicit) inlining can yield much larger gains for non-virtual calls. Implementations #4 counter-intuitively show virtual calls to be faster than non-virtual ones. If nothing else, this shows the danger of measurement artefacts. It may also show the effect of additional effort in hardware and optimisers to improve the performance of indirect function calls.

**2.3.3.1 Virtual Functions of classtemplate s**

Virtual functions of a `classtemplate` can incur overhead. If a `classtemplate` has virtual member functions, then each time the `classtemplate` is specialised it will have to generate new specialisations of the member functions, and their associated support structures such as the virtual function table.

A naïve library implementation could produce hundreds of KBytes in this case, much of which is pure replication at the instruction level of the program. The problem is a library modularity issue. Putting code into the `template` when it doesn't depend on template parameters and could be separate code, may cause each instantiation to contain potentially large and redundant code sequences. One optimisation available to the programmer is to use non-template helper functions, and describe the template implementation in terms of these helper functions.

A similar technique places non-parametric functionality that doesn’t need to be in a `template` into a non-template base class. This technique is used in several places in the standard library. Finally, it should be noted that the use of templates and the use of virtual functions are often complementary techniques, so a `classtemplate` with many virtual function should be carefully considered to determine if it might be the result of a design error.

\(^5\) The original implementation of a C++ to C translator from AT&T.
2.3.4 Inlining
The discussion above considers the cost of a function call to be a simple fact of life (it
doesn’t consider it to be overhead). However, many function calls can be eliminated
through inlining. C++ allows inlining to be explicitly requested for a function, and
popular descriptions of the language seem to encourage this for small time-critical
functions. Basically, C++’s `inline` is meant to be used as a replacement for C’s
function macros. To get an idea of the effectiveness of `inline`, we compare calls of
an inline member of a class to a non-inline member and to a macro.

<table>
<thead>
<tr>
<th>Table 2.3-3</th>
<th>#1</th>
<th>#2</th>
<th>#3</th>
<th>#4</th>
<th>#5</th>
</tr>
</thead>
<tbody>
<tr>
<td>non-inline:</td>
<td>px-&gt;g(l)</td>
<td>0.019</td>
<td>0.002</td>
<td>0.016</td>
<td>0.085</td>
</tr>
<tr>
<td>non-inline:</td>
<td>x.g(l)</td>
<td>0.019</td>
<td>0.002</td>
<td>0.016</td>
<td>0.085</td>
</tr>
<tr>
<td>inline:</td>
<td>ps-&gt;k(l)</td>
<td>0.007</td>
<td>0.002</td>
<td>0.006</td>
<td>0.005</td>
</tr>
<tr>
<td>macro:</td>
<td>K(ps, l)</td>
<td>0.005</td>
<td>0.003</td>
<td>0.005</td>
<td>0.006</td>
</tr>
<tr>
<td>inline:</td>
<td>x.k(l)</td>
<td>0.005</td>
<td>0.002</td>
<td>0.005</td>
<td>0.006</td>
</tr>
<tr>
<td>macro:</td>
<td>K(&amp;s, l)</td>
<td>0.005</td>
<td>0</td>
<td>0.005</td>
<td>0.005</td>
</tr>
</tbody>
</table>

The first observation here, is that inlining provides a significant gain over a function
call (the body of these functions is a simple expression, so this is the kind of function
where one would expect the greatest advantage from inlining). The exceptions are
implementations #2 and #5, which already have achieved significant optimisations
through implicit inlining. However, implicit inlining cannot (yet) be relied upon for
consistent high performance. For other implementations, the advantage of inlining is
significant (factors of 2.7, 2.7, and 17).

2.3.5 Multiple-Inheritance
When implementing multiple-inheritance, there is a wider array of implementation
techniques than for single-inheritance. The fundamental problem is that each call has
to ensure that the “this pointer” passed to the called function points to the correct
sub-object. This can cause time and/or space overhead. The “this pointer”
adjustment is usually done in one of two ways:

- The caller retrieves a suitable offset from the virtual function table and adds it
to the pointer to the called object, or
- a “thunk” is used to perform this adjustment. A “thunk” is a simple piece of
code that is called instead of the actual function, and which performs the
actual constant adjustment to the object pointer before transferring control to
the intended function.
<table>
<thead>

</tr>
<tr>
<td>Basel, virtual: pb-&gt;ff(i)</td>
<td>0.025</td>
<td>0.012</td>
<td>0.024</td>
<td>0.085</td>
<td>0.082</td>
</tr>
</tbody>
</table>

Here, implementations #1 and #4 managed to inline the non-virtual calls in the multiple-inheritance case, where they had not bothered to do so in the single-inheritance case. This demonstrates the effectiveness of optimisation and also that we cannot simply assume that multiple-inheritance imposes overheads.

It appears that implementations #1 and #2 don’t incur extra overheads from multiple-inheritance compared to single-inheritance. This could be caused by imposing multiple-inheritance overheads redundantly even in the single-inheritance case. However, the comparison between (single-inheritance) virtual function calls and indirect function calls in Table 2.3-2 shows this not to be the case.

Implementations #3 and #5 shows overhead when using the second branch of the inheritance tree, as one would expect to arise from a need to adjust a “this pointer”. As expected, that overhead is minor (25% and 20%) except where implementation #5 misses the opportunity to inline the call to the non-virtual function on the second branch. Again, differences between optimisers dominate differences between different kinds of calls.

### 2.3.6 Virtual Base-Classes

A virtual base-class (VBC) add additional overhead compared to a non-virtual (“ordinary”) base-class. The “adjustment” for the branch in a multiply-inheriting class can be determined statically by the implementation, so it becomes a simple add of a constant when needed. With virtual base-classes, the position of the base sub-object with respect to the complete object is dynamic, and requires more evaluation – typically with indirection through a pointer - than for the non-virtual MI adjustment.

<table>
<thead>
<tr>
<th>Table 2.3-5</th>
<th>#1</th>
<th>#2</th>
<th>#3</th>
<th>#4</th>
<th>#5</th>
</tr>
</thead>
<tbody>
<tr>
<td>SI, non-virtual: px-&gt;g(l)</td>
<td>0.019</td>
<td>0.002</td>
<td>0.016</td>
<td>0.085</td>
<td>0</td>
</tr>
<tr>
<td>VBC, non-virtual: pd-&gt;gg(i)</td>
<td>0.010</td>
<td>0.010</td>
<td>0.021</td>
<td>0.030</td>
<td>0.027</td>
</tr>
<tr>
<td>SI, virtual: px-&gt;f(l)</td>
<td>0.025</td>
<td>0.013</td>
<td>0.019</td>
<td>0.078</td>
<td>0.059</td>
</tr>
<tr>
<td>VBC, virtual: pa-&gt;f(i)</td>
<td>0.028</td>
<td>0.015</td>
<td>0.025</td>
<td>0.081</td>
<td>0.074</td>
</tr>
</tbody>
</table>

For “non-virtual function calls”, implementation #3 appears closest to the naïve expectation of a slight overhead. For implementations #2 and #5 that “slight
overhead” becomes significant because the indirection implied by the virtual base-class causes them to miss an opportunity for optimisation. There doesn’t appear to be a fundamental problem with inlining in this case, but it is most likely not common enough for the implementers to have bothered with – so far. Implementations #1 and #4 again appear to be missing a significant optimisation opportunity for “ordinary” virtual function calls. Counter intuitively, using a virtual base produces faster code!

The overhead implied by using a virtual base in a virtual call appears small. Implementations #1 and #2 keep it under 15%, implementation #4 gets that overhead to 3% but (from looking at implementation #5) that is done by missing optimisation opportunities in the “normal” single inheritance virtual function call case.

As always, simulating the effect of the language feature through other language features also carries a cost. If a programmer decides not to use a virtual base-class, yet requires a class that can be passed around as the interface to a variety of classes, an indirection is needed in the access to that interface and some mechanism for finding the proper class to be invoked by a call through that interface must be provided. This mechanism would be at least as complex as the implementation for a virtual base-class, much harder to use, and less likely to attract the attention of optimisers.

2.3.7 Type Information

Given an object of a polymorphic class (a class with at least one virtual function), a type_info object can be obtained through the use of the typeid operator. In principle, this is a simple operation involving finding the virtual function table, through that finding the most-derived-class object of which the object is part, and then extracting a pointer to the type_info object from that object’s virtual function table (or equivalent). To provide a scale, we have added the cost of a call of a global function taking one argument:

<table>
<thead>
<tr>
<th>Table 2.3-6</th>
<th>#1</th>
<th>#2</th>
<th>#3</th>
<th>#4</th>
<th>#5</th>
</tr>
</thead>
<tbody>
<tr>
<td>Global:</td>
<td>0.014</td>
<td>0</td>
<td>0.013</td>
<td>0.071</td>
<td>0.001</td>
</tr>
<tr>
<td>On base: typeid(pa)</td>
<td>0.079</td>
<td>0.047</td>
<td>0.218</td>
<td>0.365</td>
<td>0.059</td>
</tr>
<tr>
<td>On derived: typeid(pc)</td>
<td>0.079</td>
<td>0.047</td>
<td>0.105</td>
<td>0.381</td>
<td>0.055</td>
</tr>
<tr>
<td>On VBC: typeid(pa)</td>
<td>0.078</td>
<td>0.046</td>
<td>0.217</td>
<td>0.379</td>
<td>0.049</td>
</tr>
<tr>
<td>VBC on derived: typeid(pd)</td>
<td>0.081</td>
<td>0.046</td>
<td>0.113</td>
<td>0.382</td>
<td>0.048</td>
</tr>
</tbody>
</table>

There is no reason for the speed of typeid to differ depending on whether a base is virtual or not, and the implementations reflect this. Conversely, one could imagine a difference between typeid for a base-class and typeid on an object of the most derived class. Implementation #3 demonstrates this. In general, typeid seems very slow compared to a function call and the small amount of work required. We suspect this high cost is caused primarily by typeid being an infrequently used operation that so far hasn’t attracted the attention of optimiser writers.
2.3.8 Dynamic Cast

Given an object of a polymorphic class, we can cast to another sub-object of the same derived class object using a `dynamic_cast`. In principle, this operation involves finding the virtual function table, through that finding the most-derived-class object of which the object is part, and then using type information associated with that object to determine if the conversion (cast) is allowed and perform any required adjustments of the “this pointer”. In principle, this checking involves the traversal of a data structure describing the base-classes of the most derived class. Thus, the run-time of a `dynamic_cast` may depend on the relative positions in the class hierarchy of the two classes involved.

</tbody>
</table>

As with typeid, we see the immaturity of the optimiser technology. However, `dynamic_cast` is a more promising target for effort than is typeid. While `dynamic_cast` is not an operation we expect to see in a performance critical loop of a well written program, it does have the potential to be used frequently enough to warrant optimisation:

- An up-cast (cast from derived-class to base-class) can be compiled into a simple “this pointer” adjustment, as done by implementations #2 and #5.
- A down-cast (from base-class to derived-class) can be quite complicated (and therefore quite expensive in terms of run-time overhead), but many cases are simple. Implementation #5 shows that a down-cast can be optimised to the equivalent of a virtual function call, which examines a data structure to
determine the necessary adjustment of the “this pointer” (if any). The other implementations use simpler strategies involving several function calls (about 4, 10, 3, and 10 calls, respectively).

- Cross-casts (casts from one branch of a multiple-inheritance hierarchy to another) are inherently more complicated than down-casts. However, a cross-cast could in principle be implemented as a down-cast followed by an up-cast, so one should expect the cost of a cross-cast to converge on the cost of a down-cast as optimiser technology matures. Clearly the implementations have a long way to go.

### 2.4 Exception Handling

Exception Handling provides a systematic and robust approach to handling errors that cannot be handled locally at the point where they are detected.

The traditional alternatives to exception handling (in C, C++, and other languages) include:

- Returning “error codes”
- Setting error state indicators (e.g. `errno`)
- Calling error handling functions
- Escaping from a context into error handling code using `longjmp`
- Passing along a pointer to a state object with each call

When considering exception handling, it must be contrasted to the alternative ways of dealing with errors. Plausible areas of comparison include:

- Programming style
- Robustness and completeness of error handling code
- Run-time system (memory size) overheads
- Overheads from handling an individual error

Consider a trivial example:

```c
double f1(int a) { return 1/a; }
double f2(int a) { return 2/a; }
double f3(int a) { return 3/a; }
double g(int x, int y, int z) {
    return f1(x)+f2(y)+f3(z);
}
```

This code contains no error handling code. Using a variety of pre-exception error handling techniques we could detect and report errors:

```c
void error(const char* e)
{
    // handle error
}
```
double f1(int a)
{
    if (a<=0)
        error("bad input value for f1()" );
    return 1/a;
}

int error_state = 0;

double f2(int a)
{
    if (a<=0)
        error_state = 7;
    return 2/a;
}

double f3(int a, int* err)
{
    if (a<=0)
*err = 7;
    return 3/a;
}

int q(int x, int y, int z)
{
    double xx = f1(x);
    double yy = f2(y);
    if (error_state) {
        // handle error
    }
    int state = 0;
    double zz = f3(z,&state);
    if (state) {
        // handle error
    }
    return xx+yy+zz;
}

Ideally a real program would use a consistent error-handling style, but such consistency is often hard to achieve in a large program. Note that the error_state\textsuperscript{6} technique is not thread safe. Note also that it is hard to use the error() function technique effectively in programs where error() may not terminate the program. However, the key point here is that any way of dealing with errors that cannot be handled locally implies space and time overheads. It also complicates the structure of the program.

Using exceptions the example could be written like this:

```
struct Error {
    int error_number;
    Error(int n) : error_number(n) { } // constructor
};
```

\textsuperscript{6} However, some implementations do support thread-unique instances of static objects.
double f1(int a) {
    if (a<=0)
        throw Error(1);
    return 1/a;
}

double f2(int a) {
    if (a<=0)
        throw Error(2);
    return 2/a;
}

double f3(int a) {
    if (a<=0)
        throw Error(3);
    return 3/a;
}

int g(int x, int y, int z) {
    try {
        return f1(x)+f2(y)+f3(z);
    }
    catch(Error& err) {
        // handle error
    }
}

When considering the overheads of exception handling, we must remember to take into account the cost of alternative error handling techniques. Here are run times of the three variants of this trivial program on a few compilers:

| Table 2.4-1 |
|----|----|----|----|----|
|     | #1 | #2 | #3 | #4 | #5 |

**Editor’s Note:** Populate this table. Should also measure with exceptions-disabled.

The use of exceptions isolates the error-handling code from the normal flow of program execution, and unlike the error code approach, it cannot be ignored or forgotten. Also, automatic destruction of stack objects when an exception is thrown renders a program less likely to leak memory or other resources. With exceptions, once a problem is identified, it cannot be ignored – failure to catch and handle an exception results in program termination (for that reason, many programs catch all
exceptions in `main()` to ensure graceful exit from totally unexpected errors"). For a
discussion of techniques for using exceptions, see Appendix E of C++PL3.

Early implementations of Exception Handling resulted in sizeable increases in code
size and/or some run-time overhead. This led some programmers to avoid it and
compiler vendors to provide switches to suppress the use of exceptions. In some
embedded and resource-constrained environments, use of exceptions was deliberately
excluded either because of fear of overheads or because available exception
implementations didn’t meet a project’s requirements for predictability.

We can distinguish three sources of overhead:

- **try-blocks**  data and code associated with each try-block or catch-clause.

- **regular functions** data and code associated with the normal execution of
  functions that do not be needed has exceptions not existed, such as
  missed optimisation opportunities.

- **throw-expressions** data and code associated with throwing an exception.

Each source of overhead has a corresponding overhead when handling an error using
traditional error-handling techniques.

### 2.4.1 Exception Handling Implementation Issues and Techniques

The implementation of exception handling must address several issues:

- **try-block** Establishes the context for associated catch-clauses

- **catch-clause** The EH implementation must provide some run-time type-
  identification mechanism for finding catch-clauses when an exception is
  thrown.

There is some overlapping - but not identical - information needed by both
RTTI and EH features. But the EH type-information mechanism must be able
to match derived-classes to base-classes even for types without virtual
functions, and to identify built-in types such as `int`. On the other hand, the
EH type-information does not need support for *down-casting* or *cross-casting*.

Because of this overlap, some implementations require that RTTI be enabled
when EH is enabled.

- **Cleanup of handled exceptions** Exceptions, which are not re-thrown,
  must be destroyed upon exit of the catch-clause. The memory for the
  exception object must be managed by the EH implementation.

- **Automatic and temporary objects with non-trivial destructors** Destructors
  must be called if an exception occurs after construction of an object and before
  destruction, even if no try/catch is present. The EH implementation is
  required to keep track of all such objects.

---

7 Implementations vary, and on some, this does not catch exceptions that may occur during the construction or destruction of
static objects; while on others, it does.
• **Construction of objects with non-trivial destructors** If an exception occurs during construction, all completely constructed base-classes and sub-objects must be destroyed. This means that the EH implementation must track the current state of construction of an object.

• **throw-expression** A copy of the exception object being thrown must be allocated in memory provided by the EH implementation. The closest matching catch-clause must then be found using the EH type-information. Finally, the destructors for automatic, temporary, and partially constructed objects must be executed before control is transferred to the catch-clause.

• **Enforcing exception specifications** Conformance of the thrown types to the list of types permitted in the exception-specification must be checked. If a mismatch is detected, the unexpected-handler must be called.

A similar mechanism to the one implementing try/catch can be used, but if a mismatch does occur, the unexpected-handler is called.

• **operator new** After calling the destructors for the partially constructed object, the corresponding operator delete must be called if an exception is thrown during construction.

Again, a similar mechanism to the one implementing try/catch can be used.

Implementations vary in how costs are allocated across these elements.

The two main strategies are:

• the “code” approach, where code is associated with each try-block, and

• the “table” approach, that uses compiler generated static tables.

There are also various hybrid approaches. This paper discusses only the two principal implementation approaches.

2.4.1.1 The "code" Approach.

Implementations using this approach have to dynamically maintain auxiliary data-structures to manage the capture and transfer of the execution contexts, plus other dynamic data-structures involved in tracking the objects that need to be unwound in the event of an exception. Early implementations of this approach used setjmp/longjmp to return to a previous context. However, better performance can be obtained using special-purpose code. It is also possible to implement this model through the systematic use of (compiler generated) return codes.

• **try-block** Save the execution environment and reference to catch code on EH stack at try-block entry.

• **Automatic and temporary objects with non-trivial destructors** Register each constructed object together with its destructor in preparation for later destruction. Typical implementations use a linked list structure on the stack. If an exception is thrown, this list is used to determine which objects need to be destroyed.
• **Construction of objects with non-trivial destructors** One well-known implementation increments a counter for each base-class and sub-object as they are constructed. If an exception is thrown during construction, the counter is used to determine which parts need to be destroyed.

• **throw-expression** After the *catch-clause* has been found, invoke the destructors for all constructed objects in the region of the stack between the *throw-expression* and the associated *catch-clause*.

  Restore the execution environment associated with the *catch-clause*.

2.4.1.1.1 Space Overhead of the “Code” Model

• No exception-handling cost is associated with an individual object, so object size is unaffected

• Exception-handling implies a form of RTTI, which requires some increase in code and data size

• Exception-handling code is inserted into the object code for each try/catch

• Code registering the need for destruction is inserted into the object code for each stack object of a type with a non-trivial destructor

• A cost is associated with checking the *throw-specifications* of the functions that are called

2.4.1.1.2 Time Overhead of the “Code” Model

• On entry to each *try-block*
  o commit changes to variables enclosing the *try-block*
  o stack the execution context
  o stack the associated *catch-clauses*

• On exit from each *try-block*
  o remove the associated *catch-clauses*
  o remove the stacked execution context

• On entry to each *catch-clause*
  o remove the associated *catch-clauses*

• On exit from each *catch-clause*
  o retire the current exception object (destroy if necessary)

• When calling regular functions
  o if the function has an *exception-specification*, register it for checking

• As each local and temporary object is created
  o register with the current exception context as they are created

• On throw
  o locate the corresponding *catch-clause* (if any) - this involves some RTTI-like check
  If found, then:
    • destroy the registered local objects
    • check the *exception-specifications* of the functions called in-between
    • use the associated execution context of the *catch-clause*
Otherwise:
    - call the unexpected-handler

The “code” model distributes the code and associated data structures throughout the program. This means that no separate run-time support system is needed. Such an implementation can be portable and compatible with implementations that translate C++ to C or another language.

The primary disadvantages of the “code” model are that the stack space and run-time costs can be high for try-block entry; and the bookkeeping for automatic, temporary and partially constructed objects as the exception-handling stack is modified, must be done even when no exceptions are thrown. That is, code unrelated to error handling is slowed down by the mere possibility of exceptions being used. This is similar to error-handling strategies that consistently check error state or return values.

The cost of this (in this model, unavoidable) bookkeeping varies dramatically from implementation to implementation. However, one vendor reports speed impact of about 6% for a C++ to ISO C translator. This is generally considered a very good result.

2.4.1.2 The "table" Approach

Typical implementations using the static approach will generate read-only tables for determining the current execution context, locating catch-clauses, and tracking objects needing destruction:

- **try-block** This method incurs no run-time cost. All bookkeeping is pre-computed as a mapping between program counter and code to be executed in event of an exception. Tables increase program image size but may be moved away from working set to improve locality of reference. Tables can be placed in ROM, and on hosted systems with Virtual Memory, can remain swapped out until an exception is actually thrown.

- **Automatic and temporary objects with non-trivial destructors** No run-time costs associated with normal execution. Only in the event of an exception is it necessary to intrude on normal execution.

- **throw-expression** The statically generated tables are used to locate matching handlers and intervening objects needing destruction. Again, no run-time costs are associated with normal execution.

2.4.1.2.1 Space Overhead of the “Table” Model

- No exception-handling cost is associated with an object, so object size is unaffected
- Exception-handling implies a form of RTTI, implying some increase in code and data size
- This model uses statically allocated tables and some common library run-time support
- A cost is associated with checking the throw-specifications of the functions that are called
2.4.1.2.2 Time Overhead of the “Table” Model

- On entry to each try-block
  - some implementations commit changes to variables in the scopes
    enclosing the try-block - other implementations use a more
    sophisticated state table
- On exit from each try-block
  - no overhead
- On entry to each catch-clause
  - no overhead
- On exit from each catch clause
  - no overhead
- When calling regular functions
  - no overhead
- As each local and temporary object is created
  - no overhead
- On throw
  - using the tables, determine if the current frame has an appropriate
    catch-clause
    If it does, then:
    - destroy all local, temporary and partially constructed objects
      that occur between the throw-expression and the catch-clause
    - transfer control to the catch-clause
    Otherwise, check that the exception honours the exception-
    specification of the current function, and call the unexpected-handler if
    it does not.
    Otherwise, if there is a previous frame, repeat the above steps,
    otherwise call the unexpected-handler

The primary advantage of this method is that no stack or run-time costs are associated
with managing the try/catch or object bookkeeping. Unless an exception is thrown,
no run-time overhead is incurred.

Disadvantages are that the implementation is more complicated, and does not lend
itself well to implementations that translate to an intermediate language. The static
tables can be quite large. This may not be a burden on systems with virtual-memory,
but the cost can be significant for some embedded systems. All run-time costs
associated occur when an exception is thrown. However, because of the need to
examine potentially large and/or complex state tables, the time it takes to respond to
an exception may be large, variable and dependent on program size and complexity.
This needs to be factored into the probable frequency of exceptions. The extreme
case is a system optimised for infrequent exceptions where the first throw of an
exception may cause disk accesses.

One vendor reports a code and data space impact of about 15% for the generated
tables. It is possible to do better, as this vendor had no need to optimise for space.

---

8 In such implementations, this effectively makes the variables partially volatile and may prejudice other optimisations as a
result.
2.4.2 Predictability of Exception Handling Overhead

2.4.2.1 Prediction of throw/catch Performance

For some programs, the difficulty in predicting the time needed to pass control from a throw-expression to an appropriate catch clause is a problem. This uncertainty comes from the need to destroy automatic objects and - in the “table” model - from the need to consult the table. In some systems, especially those with “Real Time” requirements, it is important to be able to accurately predict how long operations will take.

For this reason current exception-handling implementations may be unsuitable for some applications. However, if the call tree can be statically determined, and the table method of EH implementation is used, it is possible to statically analyse the sequence of events necessary to transfer control from a given throw-expression to the corresponding catch-clause. Each of the events could then be statically analysed to determine their contribution to the cost, and the whole sequence of events aggregated into a single cost domain (worst-case & best-case, unbounded, indeterminate). Such analysis does not differ in principle from current time estimating methods used for non-exception code. One of the reservations expressed about EH is the unpredictable time that may elapse after a throw-expression and before control passes to the catch-clause while automatic objects are being destroyed. It is important in some systems, especially those with “Real Time” requirements, to be able to predict accurately how long operations will take.

It should be possible to accurately determine the costs of the EH mechanism itself, and the cost of any destructors invoked would need to be determined in the same way as the cost of any other functions is determined.

Given such analyses, the term “unpredictable” is inappropriate. The cost may be quite predictable, with a well-determined upper and lower bound. In some cases (recursive contexts, or conditional call trees), the cost may not be determined statically. For Real-Time applications, it is generally most important to have a determinate time domain, with a small deviation between the upper and lower bound. The actual speed of execution is often less important.

2.4.2.2 Exception Specifications

In general, an exception-specification must be checked at run-time. For example:

```c
void f(int x) throw(A,B)
{
    // whatever
}
```
will in a straightforward implementation generate code roughly equivalent to:

```c
void g(int x)
{
  try {
    // whatever
  } catch (A) {
    throw;
  } catch (B) {
    throw;
  } catch(...) {
    unexpected();
  }
}
```

In principle, static analysis (especially whole program analysis) can be used to eliminate such tests. This may be especially relevant for applications that do not support dynamic linking, are not so large or complex as to defeat analysis, and do not change so frequently as to make analysis expensive. Dependent on the implementation, empty exception-specifications can be especially helpful for optimisation.

The use of an empty *exception-specification* should reduce overheads. The caller of a function with an empty *exception-specification* can perform optimisations based on the knowledge that a called function will never throw any exception. In particular, objects with destructors in a block where no exception can be thrown need not be protected against exceptions. That is, in the “code” model no registration is needed, and in the “table” model no table entry needs to be made for that object. For example:

```c
int f(int a) throw();

char g(const string& s)
{
  string s2 = s;
  int maximum = s.size();
  int x = f(maximum);
  if (x<=0||maximum<=x)
    x = 0;
  return s2[x];
}
```

Here the compiler need not protect against the possibility of an exception being thrown after the construction of \(s_2\).

There is of course no requirement that a compiler performs this optimisation. However, a compiler intended for high-performance use is likely to perform it.

---

**Editor’s Note**: Additional text goes here, discussing how empty throw specs on the lowest level functions can be particularly helpful.

### 2.5 Templates

#### 2.5.1 Template Overheads

A *class template* or *function-template* will generate a new instantiation of code each time it is specialised with different template parameters. This can lead to an
unexpectedly large amount of code and data\textsuperscript{9}. A typical way to illustrate this problem is to create a large number of Standard Library containers to hold pointers of various types. Each type can result in an extra set of code and data being generated.

In one experiment, a program instantiating 100 instances of a single specialisation of \texttt{std::list<T>}, for some type \( T \), was compared with a second program instantiating a single instance of \texttt{std::list<T>} for 100 different types \( T \). These programs were compiled with a number of different compilers and a variety of different compiler options. The results varied widely, with one compiler producing code for the second program that was over 19 times as large as the first program; and another compiler producing code for the first program that was nearly 3 times as large as the second.

The optimisation here is for the compiler to recognise that while there may be many specialisations with different types, at the level of machine code-generation, the specialisations may actually be identical (the type system is not relevant to machine code).

While it is possible for the compiler or linker to perform this optimisation automatically, the optimisation can also be performed by the Standard Library implementation or by the application programmer.

If the compiler supports \textit{partial specialization} and \textit{member-function-templates}, the library implementer can provide \textit{partial specialisations} of containers of pointers to a single underlying implementation that uses \texttt{void*}. This technique is described in C++ PL 3rd edition.

In the absence of compiler or library support, the same optimisation technique can be employed by the programmer, by writing a \texttt{class-template} called, perhaps, \texttt{plist<T>}, that is implemented using \texttt{std::list<\texttt{void}*>}, to which all operations of \texttt{plist<T>} are delegated.

Source code must then refer to \texttt{plist<T>} rather than \texttt{std::list<T*>}, so the technique is not transparent, but it is a workable solution in the absence of tool or library support. Variations of this technique can be used with other templates too.

\subsection*{2.5.2 Templates vs. Inheritance}

Any non-trivial program needs to deal with data structures and algorithms. Because data structures and algorithms are so fundamental, it is important that their use be as simple and error-free as possible.

The template containers in the Standard C++ Library are based on principles of generic programming, rather than the inheritance approach used in other languages such as Smalltalk. An early set of foundation classes for C++, called the National Institutes of Health’s Class Library (NIHCL), was based on a class hierarchy after the Smalltalk tradition.

Of course, this was before templates had been added to the C++ language; but it is useful in illustrating how inheritance compares to templates in the implementation of programming idioms such as containers.

\textsuperscript{9} Virtual function tables, EH state tables, etc.
In the NIH Class Library, all classes in the tree inherited from a root class `Object`, which defined interfaces for identifying the real class of an object, comparing objects, and printing objects. Most of the functions were declared virtual, and had to be overridden by derived classes. The hierarchy also included a class `Class` that provided a library implementation of RTTI (which was also not yet part of the C++ language). The `Collection` classes, themselves derived from `Object`, could hold only other objects derived from `Object` which implemented the necessary virtual functions.

But the NIHCL had several disadvantages due to its use of inheritance versus templates for the implementation of container classes. The following is a portion of the NIHCL hierarchy (taken from the README file):

<table>
<thead>
<tr>
<th>NIHCL</th>

</tbody>
</table>

---

10 The `Object` class itself inherited from `class NIHCL`, which encapsulated some static data members used by all classes.

11 Presumably, had the NIHCL been written today, these would have been pure virtual functions.
Thus the class KeySortCltn (roughly equivalent to std::map), is seven layers deep in the hierarchy:

\[
\begin{align*}
\text{NIHCL} & \\
& \quad \text{Object} \\
& \quad \quad \text{Collection} \\
& \quad \quad \quad \text{SeqCltn} \\
& \quad \quad \quad \quad \text{OrderedCltn} \\
& \quad \quad \quad \quad \quad \text{SortedCltn} \\
& \quad \quad \quad \quad \quad \quad \text{KeySortCltn}
\end{align*}
\]

Because a linker cannot know which virtual functions will be called at run-time, it typically includes the functions from all the preceding levels of the hierarchy for each class in the executable program. This can lead to code bloat without templates.

There are other performance disadvantages to inheritance based collection classes:

- Primitive types cannot be inserted into the collections. Instead, these must be replaced with classes in the Object hierarchy, which are programmed to have similar behaviour to primitive arithmetic types, such as Integer and Float. This circumvents processor optimisations for arithmetic operations on primitive types. It is also difficult to exactly duplicate the behaviour of arithmetic data types through class member functions and operators.

- Because C++ has compile-time type checking, providing type-safe containers for different contained data types requires code to be duplicated for each type. Type safety is the same reason that template containers are instantiated multiple times. To avoid this duplication of code, the NIHCL collections hold pointers to a generic type - the base Object class. However, this is not type safe, and requires run-time checks to ensure objects are type compatible with the contents of the collections. It also leads to many more dynamic memory allocations, which can hinder performance. Furthermore, type checking is always dynamic adding further cost to the program using the collections.

- Because classes used with the NIHCL must inherit from Object and are required to implement a number of virtual functions, this solution is intrusive on the design of classes from the problem domain. The C++ Standard Library containers do not impose such requirements on their contents\(^{12}\). For this reason alone, the obligation to inherit from class Object often means that the use of Multiple Inheritance also becomes necessary, since domain specific classes may have their own hierarchical organization.

The C++ Standard Library lays out a set of principles for combining data structures and algorithms from different sources. Inheritance-based libraries from different vendors, where the algorithms are implemented as member functions of the containers; can be difficult to integrate and difficult to extend.

\(^{12}\) A class used in a Standard container must be assignable and copy-constructor; often it additionally needs to have a default constructor and implement \texttt{operator \&=} and \texttt{operator <}. 

Page 34 of 138
2.6 The Standard IOStreams Library - Overview

The Standard IOStreams library (§IS-27) has a well-earned reputation of being inefficient! Most of this reputation is, however, due to misinformation and naïve implementation of this library component. Rather than tackling the whole library, this report addresses efficiency considerations related to a particular aspect used throughout the IOStreams library, namely those aspects relating to the use of the Locales (§IS-22). An implementation approach for removing most, if not all, efficiency problems related to locales is discussed in 3.2.

The efficiency problems come in several forms.

2.6.1 Executable Size

Typically, using anything from the IOStreams library drags in a huge amount of library code, most of which is not actually used. The principle reason for this is the use of `std::locale` in all base classes of the IOStreams library (e.g. `std::ios_base` and `std::basic_streambuf`). In the worst case, the code for all required facets from the Locales library (§IS-22.1.1.1.1[]4) is included in the executable. A milder form of this problem merely includes code of unused functions from a facet, from which one or more functions are used. This is discussed in 3.2.2.

2.6.2 Execution Speed

Since certain aspects of IOStreams processing are distributed over multiple facets, it appears that the standard mandates an inefficient implementation. This is not the case and using some form of pre-processing, much of the work can be avoided. In addition, with a slightly smarter linker than is typically used, it is possible to remove additional inefficiencies. This is discussed in 3.2.3 and 3.2.5.

2.6.3 Object Size

The standard seems to mandate an `std::locale` object being embedded in each `std::ios_base` and `std::basic_streambuf` object, in addition to several options used for formatting and error reporting. This makes for fairly large stream objects. Using a more advanced organization for stream objects can shift the costs to those applications actually using the corresponding features. Depending on the exact approach taken, the costs are shifted to one or more of:

- compilation time
- higher memory usage when actually using the corresponding features
- execution speed

This is discussed in 3.2.6.

2.6.4 Compilation Time

A widespread approach for coping with the lack of support for the separation model is to include the template implementations in the headers. This can result in very long compile and link times if, for example, the IOStreams headers are included, and especially if optimisations are enabled. With an improved approach using pre-
instantiation and consequent decoupling techniques, the compile-time can be reduced significantly. This is discussed in 3.2.4.
3 Performance – Techniques & Strategies

3.1 Programmer Directed Optimisations

There are many factors that influence the performance of a computer program. At one end of the scale is the high-level design and architecture of the overall system, at the other is the raw speed of the hardware and operating system software on which the program runs. Assuming that the applications programmer has no control over these factors in the system, what can be done at the level of writing code to achieve better performance?

Compilers typically use a heuristic process in optimising code that may be different for small and large programs. Therefore, it is difficult to recommend any techniques that are guaranteed to improve performance in all environments. It is vitally important to measure a performance-critical application in the target environment and concentrate on improving performance where bottlenecks are discovered. Because so many factors are involved, measuring actual performance can be difficult but remains an essential part of the performance tuning process.

The best way to optimise a program is to use space- and time-efficient data structures and algorithms. For example, changing a sequential search routine to a binary search will reduce the average number of comparisons required to search a sorted \( N \)-element table from about \( N/2 \) to just \( \log_2 N \). For \( N = 1000 \), this is a reduction from 500 comparisons to 10. For \( N = 1,000,000 \), the average number of comparisons is 20.

Another example is that `std::vector` is a more compact data structure than `std::list`. A typical `std::vector<int>` implementation will use about three words plus one word per element, whereas a typical `std::list<int>` implementation will use about two words plus three words per element. That is, assuming `sizeof(int)==4`, a standard vector of 1,000 `int`s will occupy approximately 4,000 bytes, whereas a list of 1,000 `int`s will occupy approximately 12,000 bytes. Thanks to cache and pipeline effects, traversing such a vector will be much faster than traversing the equivalent list. Typically, the compactness of the vector will also assure that moderate amounts of insertion or erasure will be faster than for the equivalent list. There are good reasons for vector being recommended as the default standard library container.

The C++ Standard Library provides several different kinds of containers, and guarantees how they compare at performing common tasks. For example, inserting an element at the end of a `std::vector` takes constant time\(^\text{13}\), but inserting one at the beginning or in the middle takes linear time increasing with the number of elements that have to be moved to make space for the new element. With an `std::list` on the other hand, insertion of an element takes constant time at any point in the collection,

\(^{13}\) It takes constant time unless the addition forces the vector to reallocate storage, but reallocation can be prevented by pre-allocating space with `reserve()`.
but that constant time is somewhat slower than adding one to the end of a vector. Finding the Nth element in an std::vector involves a simple constant-time arithmetic operation on a random-access iterator accessing contiguous storage, whereas an std::list would have to be traversed one element at a time, so access time grows linearly with the number of elements. A typical implementation of std::map maintains the elements in sorted order in a “red-black” tree structure, so access to any element takes logarithmic time. Though not a part of the C++ Standard Library, std::hash_maps are capable of faster lookups than an std::map, but are dependent on a well-chosen hash function and bucket size. Poor choices can degrade performance significantly.

Always measure before attempting to optimise. It is very common for even experienced programmers to guess incorrectly about performance implications of choosing one kind of container over another. Often performance depends critically on the machine architecture and the quality of optimiser used.

The C++ Standard Library also provides a large number of algorithms with documented complexity guarantees. These are functions that apply operations to a sequence of elements. Achieving good performance, as well as correctness, is a major design factor in these algorithms. These can be used with the standard containers, or with native arrays, or with newly written containers, provided they conform to the standard interfaces.

If profiling reveals a bottleneck, small local code optimisations may be effective. But it is very important always to measure first. Transforming code to reduce run time or space consumption can often decrease program readability, maintainability, modularity, portability, and robustness as well. Such optimisations often sacrifice important abstractions in favour of improving performance, but while the performance cost may be reduced, the cost to program structure and maintainability needs to be factored into the decision to rewrite code to achieve other optimisation goals.

An old rule of thumb is that there is a trade-off between program size and execution speed - that techniques such as declaring code inline can make the program larger but faster. But now that processors make extensive use of on-board cache and instruction pipelines, so the smallest code is often the fastest as well. Compilers are free to ignore inline directives and to make their own decisions about which functions to inline, but adding the hint is often useful as a portable performance enhancement. With small one- or two-line functions, where the implementation code generates fewer instructions than a function preamble, the resulting code may well be both smaller and faster.
Programmers are sometimes surprised when their programs call functions they haven't specified, maybe even haven't written. Just as a single innocuous-looking line of C code may be a macro that expands do dozens of lines of code, possibly involving system calls which trap to the kernel with resulting performance implications, a single line of C++ code may also result in a sequence of function calls which is not obvious without knowledge of the full program. Simply declaring a variable of user-defined type such as:

```cpp
X v1;       // looks innocent
x v2 = 7;   // obviously initialised
```

However, the declaration of `v1` implicitly invokes the class `X`'s default constructor to initialise the object `v1`. Depending on the class design, proper initialisation may involve memory allocations or system calls to acquire resources\(^{14}\). It is important to remember however, that in C the object would still need to be initialised, and that code would have to be explicitly called by the programmer. Resources would also have to be explicitly released at the appropriate time. The initialisation and release code is more visible to the C programmer, but possibly less robust because the language does not support it automatically.

Understanding what a C++ program is doing is important for optimisation. If you know what functions C++ silently writes and calls, careful programming can keep the unexpected code to a minimum. Some of the works cited in the bibliography (Appendix C) provide more extensive guidance, but the following provides some suggestions for writing more efficient code:

- Shift expensive computations from the most time-critical parts of a program to the least time-critical parts (often, but not always, program start-up). Other techniques include lazy evaluation and caching of pre-computed values. Of course, these strategies apply to programming in any language, not just C++.

- In constructors, prefer initialisation of data members to assignment. If a member has a default constructor, that constructor will be called to initialise the member before any assignment takes place. Therefore, an assignment to a member within the constructor body can mean that member is initialised as well as assigned to, effectively doubling the amount of work done.

- As a general principle, don't define a variable before you are ready to initialise it. Defining it early results in a constructor call (initialisation) followed by an assignment of the value needed, as opposed to simply constructing it with the value needed.

- Understand how and when the compiler generates temporary objects. Often small changes in coding style can prevent the creation of temporaries, with consequent benefits for run-time speed and memory footprint. Temporary objects may be generated when initialising objects, passing parameters to functions, or returning values from functions.

\(^{14}\) This is a common idiom in C++, because the release of the resources can be triggered automatically when the object’s lifetime ends (§13-3.7).
• Passing arguments to a function by value [e.g. \texttt{void f(T x)}] is cheap for built-in types, but potentially expensive for class types since they may have a non-trivial copy constructor. Passing by address [e.g. \texttt{void f(T const* x)}] is light-weight, but changes the way the function is called. Passing by reference-to-const [e.g. \texttt{void f(T const\& x)}] combines the safety of passing by value with the efficiency of passing by address.

• Calling a function with a type that differs from the function’s declared argument type implies a conversion. Note that such a conversion can require work to be done at run-time. For example:

\begin{verbatim}
void f1(double);
f1(7.0);  // no conversion (pass by value implies copy)
f1(7);    // conversion: f1(double(7))

void f2(const double&);
f2(7.0);  // no conversion
f2(7);    // means: const double tmp = 7;  f(tmp);

void f3(std::string);
string s = "NES";
f3(s);    // no conversion (pass by value implies copy)
f3("NES");  // conversion: f3(string("NES"))

void f4(const std::string&);
f4(s);    // no conversion (pass by reference, no copy)
f4("AS");  // means: const string tmp = "AS";  f4(tmp);
\end{verbatim}

If a function is called several times with the same value, it can be worthwhile to put the value in a variable of the appropriate type (such as \texttt{s} in the example above) and pass that. That way, the conversion will be done once only.

• Unless you need automatic type conversions, declare all one-argument constructors\footnote{This refers to any constructor that may be called with a single argument. Multiple parameter constructors with default arguments can be called as one-argument constructors.} \texttt{explicit}. This will prevent them from being called accidentally. Conversions can still be done when necessary by explicitly stating them in the code, thus avoiding the penalty of hidden and unexpected conversions.

• Rewriting expressions can reduce or eliminate the need for temporary objects. For example, if \texttt{a}, \texttt{b}, and \texttt{c} are objects of \texttt{class Matrix}:

\begin{verbatim}
Matrix a;    // \texttt{inefficient}: don't create an object before
            // it is really needed, default initialisation
            // can be expensive
a = b + c;  // \texttt{inefficient}: (b + c) creates a temporary
            // object and then assigns it to \texttt{a}
Matrix a = b; // \texttt{better}: no default initialisation
a += c;     // \texttt{better}: no temporary objects created
\end{verbatim}

Better yet, use a library that eliminates need for the rewrite using \texttt{+=}. Such libraries, which are common in the numeric C++ community, usually use function objects and expression templates to yield uncompromisingly fast code from conventional-looking source.
• Use the return value optimisation to give the compiler a hint that temporary objects can be eliminated. The trick is to return constructor arguments instead of objects, like this:

```cpp
const Rational operator *( Rational const & lhs,
                           Rational const & rhs )
{
    return Rational( lhs.numerator() * rhs.numerator(),
                     lhs.denominator() * rhs.denominator() );
}
```

Less carefully written code might create a local `Rational` variable to hold the result of the calculation, use the assignment operator to copy it to a temporary variable holding the return value, then copy that into a variable in the calling function.

```cpp
// not this way ...
const Rational operator *( Rational const & lhs,
                           Rational const & rhs )
{
    Rational tmp; // calls the default constructor (if any)
    tmp.my_numerator = lhs.numerator() * rhs.numerator();
    tmp.my_denominator = lhs.denominator() * rhs.denominator();
    return tmp;
}
```

But with the suggested hints, the compiler is able to construct the return value directly into the variable that is specified to receive it.

• Prefer pre-increment and -decrement to postfix operators.

Postfix operators like `i++` copy the existing value to a temporary object, increment the internal value, and then return the temporary. Prefix operators like `++i` increment the actual value first and return a reference to it. With objects such as iterators, creating temporary copies is expensive compared to built-in `ints`.

```cpp
for ( list<X>::iterator it = mylist.begin();
     it != mylist.end(); ++it ) // NOTE: rather than it++
{
    // ...
}
```

• Dynamic memory allocation and de-allocation can be a bottleneck. Consider writing class-specific `operator new()` and `operator delete()` functions, optimised for objects of a specific size or type. It may be possible to recycle blocks of memory instead of releasing them back to the heap whenever an object is deleted.

• Sometimes it is helpful to “widen” a class' interface with functions that take different data types to prevent automatic conversions (such as adding an overload on `char *` to a function which takes an `std::string` parameter). The numerous overloads for operators `+`, `==`, `!=`, and `<` in the `<string>` header
are an example of such a "fat" interface\textsuperscript{16}. If the only supported parameters were \texttt{std::string}s, then characters and pointers to character arrays would have to be converted to full \texttt{std::string} objects before the operator was applied.

- The Standard \texttt{std::string} class is not a lightweight component. Because it has a lot of functionality, it comes with a certain amount of overhead (and because Standard Library container classes throw C++ \texttt{std::string}s, and not C-style string literals, this overhead may be included in a program inadvertently).

In many applications, strings are created, stored, and referenced, but never changed. As an extension, or as an optimisation, it might be useful to create a lighter-weight unchangeables string class.

- Reference counting is a widely used optimisation technique. In a single-threaded application, it can prevent making unnecessary copies of objects. However, in multi-threaded applications, the overhead of locking the shared data representation may add unnecessary overheads, negating the performance advantage of reference counting\textsuperscript{17}.

- Pre-compute values that won't change. To avoid repeated function calls inside a loop, rather than writing:

  ```cpp
  while( myListIterator != myList.end() ) ... 
  for( size_t n = 0; n < myVector.size(), ++n ) ... 
  ```

instead call \texttt{myList.end()} or \texttt{myVector.size()} once before the loop, storing the result in a variable which can then be used in the comparison., for example:

```cpp
std::list<myT> myEnd = myList.end(); 
while( myListIterator != myEnd ) ... 
```

On the other hand, if a function such as \texttt{myList.end()} is so simple that it can be inlined, the rewrite may not yield any performance advantage over what a good compiler would produce for the original code.

\textsuperscript{16} It is also worth noting, that even if a conversion is needed, it is sometimes better to have the conversion performed in one place, where an overloaded “wrapper” function calls the one that really performs the work. This can help to reduce program size, where each caller would otherwise perform the conversion.

\textsuperscript{17} Of course, if space is the resource being optimised, reference counting may still be the best choice.
• Object-oriented programming often leads to a number of small functions per
class, often with trivial implementation. For example:

```cpp
class X
{
  private:
    int  value_;  // pointer to array of [size] doubles
    double* array_;  // pointer to array of [size] doubles
    size_t  size_;  // size

  public:
    int value() { return value_; }
    size_t size() { return size_; }
    // ...
};
```

Small forwarding functions can usually be inlined to advantage, especially if
they occupy less code space than preparing the stack frame for a function call.
As a rule of thumb, functions consisting of only one or two lines are generally
good candidates for inlining.

• When processors read-ahead to maintain a pipeline of instructions, too many
function calls can slow down performance because of branching or cache
misses. Optimisers work best when they have stretches of sequential code to
analyse, because it gives them more opportunity to use register allocation,
code-movement, and common sub-expression elimination optimisations. This
is why inline functions can help performance, as inlining exposes more
sequential code to the optimiser. Techniques such as avoiding conditional
code, and unrolling short loops also help the optimiser do a better job.

• The use of dynamic binding and virtual functions has some overhead in both
memory footprint and run-time performance. This overhead is minor,
especially when compared against alternative ways of achieving run-time
polymorphism (§2.3.3). A bigger factor is that virtual functions may interfere
with compiler optimisations and inlining.

Note that virtual functions should be used only when run-time polymorphic
behaviour is desired. Not every function needs to be virtual and not every
class should be designed to be a base-class.
Many programs written in some conventional (also called “old fashioned”) object-oriented styles are very slow to compile, because the compiler must examine hundreds of header files and tens of thousands of lines of code. In principle, this can be avoided. However, code can be structured to minimize re-compilation after changes. This typically produces better and more maintainable designs, because they exhibit better separation of concerns.

Consider a classical example of an object-oriented program:

```cpp
class Shape {
public:   // interface to users of Shapes
    virtual void draw() const;
    virtual void rotate(int degrees);
    // ...
protected:   // common data (for implementers of Shapes)
    Point center;
    Color col;
    // ...
};
class Circle : public Shape {
public:
    void draw() const;
    void rotate(int) { }
    // ...
protected:
    int radius;
    // ...
};
class Triangle : public Shape {
public:
    void draw() const;
    void rotate(int);
    // ...
protected:
    Point a, b, c;
    // ...
};
```

The idea is that users manipulate shapes through Shape's public interface, and that implementers of derived-classes (such as Circle and Triangle) share aspects of the implementation represented by the protected members.

It is not easy to define shared aspects of the implementation that are helpful to all derived-classes. For that reason, the set of protected members is likely to need changes far more often than the public interface. For example, even though center is arguably a valid concept for all Shapes, it is a nuisance to have to maintain a point center for a Triangle - for triangles, it makes more sense to calculate the center if and only if someone expresses interest in it.

The protected members are likely to depend on implementation details that the users of Shape would rather not have to depend on. For example, much code using a Shape will be logically independent of the definition of Color, yet the presence of Color in the definition of Shape will probably require compilation of header files defining the operating system's notion of colour.
When something in the protected part changes, users of Shape have to recompile – even though only implementers of derived-classes have access to the protected members. Thus, the presence of "information helpful to implementers" in the base-class that also acts as the interface to users is the source of several problems:

- instability in the implementation,
- spurious recompilation of user code (when implementation information changes), and
- excess inclusion of header files into user code (because the "information helpful to implementers" needs those headers).

This is sometimes known as the "brittle base-class problem".

The obvious solution is to omit the "information helpful to implementers" for classes that are used as interfaces to users. In other words, interface classes should represent “pure” interfaces and therefore take the form of abstract classes, thus:

```cpp
class Shape {
public: // interface to users of Shapes
    virtual void draw() const = 0;
    virtual void rotate(int degrees) = 0;
    virtual Point center() const = 0;
    // ...
    // no data
};

class Circle : public Shape {
public:
    void draw() const;  
    void rotate(int) { }  
    Point center() const { return center; }
    // ...
protected:
    Point cent;
    Color col;
    int radius;
    // ...
};

class Triangle : public Shape {
public:
    void draw() const;
    void rotate(int);
    Point center() const;
    // ...
protected:
    Color col;
    Point a, b, c;
    // ...
};
```

The users are now insulated from changes to implementations of derived-classes. This technique has been known to decrease build times by orders of magnitude.
But what if there really is some information that is common to all derived classes (or even to several derived classes)? Simply make that information a class and derive the implementation classes from that also:

```cpp
class Shape {
    public: // interface to users of Shapes
        virtual void draw() const = 0;
        virtual void rotate(int degrees) = 0;
        virtual Point center() const = 0;
        // ...
        // no data
    }

    struct Common {
        Color col;
        // ...
    }

    class Circle : public Shape, protected Common {
        public:
            void draw() const;
            void rotate(int) {
                Point center() const { return center; }
            }
            // ...
        protected:
            Point cent;
            int radius;
    }

    class Triangle : public Shape, protected Common {
        public:
            void draw() const;
            void rotate(int);
            Point center() const;
            // ...
        protected:
            Point a, b, c;
    }
```

- Another technique for ensuring better separation between parts of a program involves an interface object holding a single pointer to an implementation object. This is often called “the PIMPL” (Pointer to IMPLementation) idiom. For example:

```
missing example
```

---

**Editor’s Note:** More text on the way here.

- Use function objects with the Standard Library algorithms rather than function pointers. Function pointers defeat the data flow-analysers of many optimisers, but function objects are passed by value and optimisers can easily handle inline functions on objects.

- Calling a function with a default argument requires the constructor to create a temporary object for the default. If the construction of that temporary is expensive and if the function is called several times, it can be worth while to

---

18 Or even “The Cheshire Cat”
construct the default argument value somewhere and use that value in each call. For example:

```cpp
class C
{
public:
    C(int i) { ... }  // ... 
    int mf() const;
};

int f(const C & x = C()) { // construct C(0) in each call f()
    return x.mf();
}

int g() {  // construct x in the first call
    static const C x0();   // construct x0 for use in calls of h()
    int h(const C& x = x0) {
        return x.mf();
    }
```

- When programming "close to the metal", such as when dealing with low-level hardware devices, some use of assembly code may be unavoidable. C++'s `asm` keyword enables the use of assembler to be kept to the necessary minimum. The syntax of an `asm declaration` (§15.7.4) is:

  ```
  asm-definition:
  asm ( string-literal ) ;
  ```

  The assembler statement is typically enclosed in quotation marks. The meaning of an `asm declaration` is implementation defined. Typically, it is used to insert assembly language directly into the translator output. Needless to say, it is highly non-portable.

  The advantage of using short assembler functions can be lost if they have to be placed in separate source files where the efficiency gained is over-shadowed by the overhead of calling and returning a function, plus attendant effects on the instruction pipeline and register management. The `asm` keyword can insert just a few assembler statements inline where they provide the most benefit.

  Typically, a compiler is not aware of the semantics of inlined assembly instructions. Thus, use of an `asm declaration` can defeat other important optimisations such as common sub-expression elimination and global en-registering. Consequently, assembler inserts should typically be used only for operations that cannot be expressed in C++.

- Whenever possible, compute values and catch errors at translation time rather than run-time. With sophisticated use of templates, a complicated block of code can be compiled to a single constant in the executable, therefore having
zero run-time overhead. This might be described as a code implosion (the opposite of a code explosion). For example

```cpp
template <int N>
class Factorial {
    public:
        enum { value = N * Factorial<N-1>::value };
};

class Factorial<1> {
    public:
        enum { value = 1 };
};
```

Using this class\(^{19}\), the value \(N!\) is accessible at compile-time as Factorial\(<N>::value.

As another example, the following \textit{class template} can be used to generate a compile-time constant Square Root Computation: \texttt{ceil(sqrt(N))}:

```cpp
// <root.h>:
template <int Size, int Low = 1, int High = Size>
struct Root;

template <int Size, int Mid>
struct Root<Size,Mid,Mid> {
    static const int root = Mid;
};

template <int Size, int Low, int High>
struct Root {
    static const int mean = (Low + High)/2;
    static const bool down = (mean * mean >= Size);
    static const int root = Root<Size,
        (down ? Low : mean + 1),
        (down ? mean : High)>::root;
};

// User code:
// compute sqrt(N), use it for static table size
int table[Root<N>::root];
```

Template meta-programming and expression templates are not techniques for novice programmers, but an advanced practitioner can use them to good effect.

- Templates provide compile-time polymorphism, wherein type selection does not incur any run-time penalty. If appropriate to the design, consider using templates as interfaces instead of abstract base-classes\(^{20}\). Templates have several useful properties: they impose no space or code overhead on the class used as a template argument, and they can be attached to the class for limited times and purposes. If the class does not provide the needed functionality, it can be defined externally through template specialization. If certain functions in the template interface are never used for a given class, they need not be

\(^{19}\) Within limitations, remember that if an \texttt{enum} is 32-bits, the maximum \(N\) can be is just 12.

\(^{20}\) On the other hand, if run-time as opposed to compile-time polymorphism is needed, then using virtual functions is more appropriate.
defined because they will not be instantiated. In the example below, the talk_in_German() function in the "interface" is only defined for class CuckooClock, because that is the only object for which it is needed. Invoking talk_in_German() on an object of a different type results in a compiler diagnostic:

```cpp
#include <iostream>
using std::cout;
using std::endl;

// some domain objects
class Dog {
public:
    void talk() { cout << "woof woof" << endl; }
};

class CuckooClock {
public:
    void talk() { cout << "cuckoo cuckoo" << endl; }
    void talk_in_German() { cout << "wachet auf!" << endl; }
};

class BigBenClock {
public:
    void talk() { cout << "take a tea-break" << endl; }
    void playBongs() { cout << "bing bong bing bong" << endl; }
};

class SilentClock {
    // doesn't talk
};

// generic template to provide non-inheritance-based polymorphism
template <class T> class Talkative {
T& t;
public:
    Talkative( T& obj ) : t( obj ) { }
    void talk() { t.talk(); }
    void talk_in_German() { t.talk_in_German(); }
};

// specialization to adapt functionality
template <>
class Talkative<BigBenClock> {
    BigBenClock& t;
public:
    Talkative( BigBenClock& obj ) : t( obj ) { }
    void talk() { t.playBongs(); }
};
```
// specialization to add missing functionality
template <>
class Talkative< SilentClock >
{
    SilentClock & t;
public:
    Talkative( SilentClock & obj )
    : t( obj )
    { }
    void talk() { cout << "tick tock" << endl; }
};

// adapter function to simplify syntax in usage
template <class T>
Talkative<T> makeTalkative( T & obj )
{
    return Talkative<T>( obj );
}

// function to use an object which implements the
// Talkative template-interface
template <class T>
void makeItTalk( Talkative<T> t )
{
    t.talk();
}

template<>

int main()
{
    Dog aDog;
    CuckooClock aCuckooClock;
    BigBenClock aBigBenClock;
    SilentClock aSilentClock;

    Talkative<Dog> td( aDog );
    td.talk();  // woof woof

    Talkative<CuckooClock> tcc( aCuckooClock );
    tcc.talk();  // cuckoo cuckoo

    makeTalkative( aDog ).talk();  // woof woof
    makeTalkative( aCuckooClock ).talk_in_German();  // wahcet
    // auf!

    makeItTalk( makeTalkative( aBigBenClock ) );  // bing bong
    // bing bong
    makeItTalk( makeTalkative( aSilentClock ) );  // tick tock

    return 0;
}

- Controlling the instantiation of class-templates and function-templates can help to reduce the footprint of a program. Some compilers instantiate a template only once into a separate "repository"; others instantiate every template into every translation unit. In the latter case, the linker typically eliminate duplicates. If it does not, the executable can suffer significant memory overheads.

- Explicit instantiation of a class template specialisation causes instantiation of all of its members into the translation unit containing the explicit instantiation directive. In addition to a whole class template, explicit instantiation can also
be used for a member function, member class, or static data member of a
\textit{class-template}, or a \textit{function-template} or member template specialisation.

For example (from IS-14.7.2\cite{12}):

\begin{verbatim}
#include <algorithm>
#include <vector>
#include <iostream>

using namespace std;

namespace N {
    template<class T> class Array { void mf(); }
    template class Array<char>;
    template void Array<int>::mf();

    template<class T> void sort(Array<T>& v) { /* ... */ }
    template void sort(Array<char>&); // argument is deduced here
}

namespace M {
    template<class T> void f(T&); // for some reason
}

namespace N {
    template void N::f<int>(int&); // for some reason
}
\end{verbatim}

Instantiating template code into a library \textbf{once} can save space in every
translation unit which links to it. For example, in their runtime libraries, some
library vendors provide instantiations of \texttt{std::basic_string<char> and}
\texttt{std::basic_string<wchar_t>}. Some compilers also have command-line
options to force complete template instantiation or to suppress it as needed.

- In addition to these portable coding techniques, programming tools offer
  additional platform-specific help for optimising programs. Some of the
techniques available include the following:
  - Compiler options are usually extra arguments or switches, which pass
    instructions to the compiler. Some of these instructions are related to
    performance, and control how to:
      - generate executable code optimised for a particular hardware
        architecture.
      - optimise the translated code for size or speed. Often there are
        sub-options to exercise finer control of optimisation techniques
        or how aggressively they should be applied.
      - suppress the generation of debugging information, which can add
to code and data size.
      - instrument the output code for run time profiling, as an aid to
        measuring performance and to refine the optimisation strategies
        used in subsequent builds.
      - disable exception-handling overhead in code which does not
        use exceptions at all.
      - control the instantiation of templates.
#pragma directives allow compilers to add features specific to machines and operating systems, within the framework of Standard C++. Some of the optimisation-related uses of #pragma directives are to:

- specify function calling conventions (a C++ linkage-specification can also be used for this purpose).
- influence the inline expansion of code.
- specify optimisation strategies on a function-by-function basis.
- control the placement of code or data into memory areas (to achieve better locality of reference at run time).
- affect the layout of class members (through alignment or packing constraints, or by suppressing compiler-generated data members).

Note that #pragmas are not standardised and are not portable.

- Linking to static libraries or shared libraries, as appropriate. Linker options can also be used to control the amount of extra information included in a program (e.g., symbol tables, debugging formats).
- Utilities for efficiently allocating small blocks of memory. These may take the form of system calls, #pragmas, compiler options, or libraries.
- Additional programs:
  - Many systems have a utility program\(^{21}\) to remove the symbol table and line number information from an object file, once debugging is complete (This can also be done at link time by the linker). The purpose is to reduce file storage and in some cases, memory overhead.
  - Some systems have utilities\(^{22}\) and tools to interpret profiling data and identify run time bottlenecks.

- Sometimes, minimising compile time is important. When code is being created and debugged, suppressing optimisation may enable the compiler to run faster.

The most effective technique for reducing compile time relies on reducing the amount of code to be compiled. The key is to reduce coupling between different parts of a program so that header files are small and so that few header files are needed in most translation units. Techniques for accomplishing that are the use of abstract classes as interfaces and the PIMPL idiom.

\(^{21}\) For instance the ‘strip’ utility which is part of the Software Development Utilities option in the IEEE Posix/Open Group Unix specifications.

\(^{22}\) For instance the ‘prof’ utility which is part of the Posix/Unix Standard, but is available on many systems.
As discussed above, suppressing automatic template instantiation in a given translation unit may reduce compile-time.

- Reading and parsing header code takes time. Years ago, the common practice was to #include as few headers as possible, so that only necessary symbols were declared. But with technology to pre-compile headers, build time may be reduced by using a single header in each translation unit which #includes everything needed for the program. Furthermore, most compilers now implement the following “idem potent guard” optimisation. Well-designed headers will usually protect their contents against multiple inclusion by following this pattern:

```
#if !defined THIS_HEADER_H
#define THIS_HEADER_H
  // here are the contents of the header
#endif /* THIS_HEADER_H */
```

If the compiler provides this “idem potent guard” optimisation, it will record in an internal table the fact that this header has an idem potent guard. If this header is subsequently #included again, and the macro THIS_HEADER_H still remains defined, then the compiler can avoid accessing the header contents.

For more details about the “idem potent guard” optimisation, a sample test program, and ongoing test results, see Bob Archer’s discussion at:

http://www.hottub.demon.co.uk/software/include/index.htm

If the compiler does not perform this optimisation, the check can be implemented by the programmer:

```
#if !defined MY_HEADER_H
#include "my_header.h"
#endif
```

This has the disadvantage of coupling the header’s guard macro to the source files which #include that header.

As always, local measurements in specific circumstances should govern the decision. But be careful not to create unnecessary temporary objects by using an argument that must be converted to the type of the function parameter, for example:

```c
void f( const double& );
f( 7 );

// is effectively:
cost double tmp = 7;
f( tmp );
```

**Editor’s Note:** Why has the following programmer directed optimisation been removed? It appears to me that this still holds true.

- Use the direct initialisation syntax T a(b); rather than the copy initialisation syntax T a = b;. Copy-initialisation is permitted to create an intermediate temporary object, while direct initialisation is not (§14.6.8). Effectively,
when \( b \) is not of type \( T \), copy-initialisation \( T \ a = b; \) implies a sequence such as:

\[
T \ tmp( b ); // create a temporary object of type T \\
T \ a( \ tmp ); // initialise a from tmp using T's copy constructor
\]

In practice, the compiler often elides the temporary object, but using the direct-initialisation syntax will avoid any chance of a temporary being created.

### 3.2 Optimising Libraries: Reference Example: 
"An Efficient Implementation of Locales and IOSTreams"

The definition of \( Locales \) in the C++ Standard (§15.2) seems to imply a pretty inefficient implementation. This is however not true. It is possible to create efficient implementations of the \( Locales \) library, both in terms of run-time efficiency and executable size. This does take some thought and this reports discusses some of the possibilities that can be used to improve the efficiency of \( \text{std}::\text{locale} \) implementations with a special focus on the functionality as used by the IOSTream library.

The approaches discussed in this report are primarily applicable to statically bound executables as are typically found in for example, embedded systems. If shared, or dynamically loaded libraries are used, different optimisation goals have precedence, and some of the approaches described here could be counterproductive. Clever organization of the shared libraries might deal with some efficiency problems too - however, this is not discussed in this report.

Nothing described in this report involves magic or really new techniques. It just discusses how well known techniques may be employed to the benefit of the library user. It does however involve additional work compared to a trivial implementation, for the library implementer as well as for the library tester, and in some cases for the compiler implementer. Some of the techniques focus on just one efficiency aspect and thus not all techniques will be applicable in all situations (e.g. certain performance improvements can result in “additional” code). Depending on the requirements, the library writer or possibly even the library user, has to choose which optimisations are the most appropriate.

#### 3.2.1 Locale Implementation Basics

Before going into the details of the various optimisations, it is worth introducing the implementation of locales describing features implicit to the Standard definition. Although some of the material presented in this section is not strictly required and there are other implementation alternatives, this section should provide the necessary details to understand where the optimisations should be directed.

An \( \text{std}::\text{locale} \) object is an immutable collection of immutable objects - or more precisely - of immutable facets. This immutability trait is important in multi-threaded environments, because it removes the need to synchronize most accesses to locales and their facets. The only operations needing multi-threading synchronization are copying, assigning, and destroying \( \text{std}::\text{locale} \) objects and the creation of modified locales.
Instead of modifying a locale object to augment the object with a new facet or to replace an existing one, `std::locale` constructors or member functions are used, creating new locale objects with the modifications applied. As a consequence, multiple locale objects can share their internal representation and multiple internal representations can (in fact, have to) share their facets. When a modified locale object is created, the existing facets are copied from the original and then the modification is applied, possibly replacing some facets. For correct maintenance of the facets, the Standard mandates the necessary interfaces, allowing reference counting or some more or less equivalent techniques for sharing facets. The corresponding functionality is implemented in the class `std::locale::facet`, the base-class for all facets.

Copying, assigning, and destroying `std::locale` objects reduces to simple pointer and reference count operations. When copying a locale object, the reference count is incremented and the pointer to the internal representation is assigned. When destroying a locale object, the reference count is decremented and when it drops to 0, the internal representation is released. Assignment is an appropriate combination of these two. What remains is the default construction of an `std::locale` which is just the same as a copy of the current global locale object. Thus, the basic lifetime operations of `std::locale` objects are reasonably fast.

Individual facets are identified using an ID, more precisely an object of type `std::locale::id` which is available as a static data member in all base classes defining a facet. A facet is a class derived from `std::locale::facet` which has a publicly accessible static member called `id` of type `std::locale::id` ([ISO-22.1.1.1.2][1]). Although explicit use of a locale's facets seems to use a type `F` as an index, the Locales library internally uses `F::id`. The `std::locale::id` simply stores an index into an array identifying the location of a pointer to the corresponding facet or 0 if a locale object does not store the corresponding facet.
Taken together, a locale object is basically a reference counted pointer to an internal representation consisting of an array of pointers to reference counted facets. In a multi threaded environment, the internal representation, and the facets might store a mutex (or some similar synchronization facility) thus protecting the reference count. A corresponding excerpt of the declarations might look something like this (with \texttt{name} and other qualifications or elaborations of names omitted):

```cpp
namespace std {

class locale {
public:
    class facet {
        // ...
        private:
            size_t refs;
            mutex lock; // optional
    }

    class id {
        // ...
        private:
            size_t index;
    }

    // ...
    private:
        struct internal {
            // ...
            size_t refs;
            mutex lock; // optional
            facet* members;
        }
        internal* rep;
    };

These declarations are not really required and there are some interesting variations:

- Rather than using a double indirection with an internal \texttt{struct}, a pointer to an array of unions can be used. The union would contain members suitable as reference count and possible mutex lock, as well as pointers to facets. The index 0 could, for example, be used as “reference count” and index 1 as “mutex”, with the remaining array members being pointer to facets.

- Instead of protecting each facet object with its own mutex lock, it possible to share the locks between multiple objects. For example, there may be just one global mutex lock, because the need to lock facets is actually relatively rare (only when a modified locale object is necessary is there a need for the mutex) and it is unlikely that this global lock remains held. If this is too coarse grained, it is possible to place a mutex lock into the static \texttt{id} object, such that an individual mutex lock exists for each facet type.

- If atomic increment and decrement/check are available, the reference count is sufficient, because the only operations needing multi-threading protection are incrementing and decrementing the reference count.

- The locale objects only need a representation if there are modified locale objects. If such an object is never created, it is possible to use an empty
std::locale object. Whether or not this is the case can be determined using some form of "whole program optimisation" (§3.2.5).

- Whether an array or some other data structure is used internally does not really matter. What is important is that there is a data structure indexed by std::locale::id.

- A trivial implementation could use a null pointer to indicate that a facet is absent in a given locale object. If a pointer to a dummy facet is used instead, std::use_facet() can simply use a dynamic_cast<> to produce the corresponding std::bad_cast exception.

In any case, it is reasonable to envision a locale object as being a reference counted pointer to some internal representation containing an array of reference counted facets. Whether this is actually implemented so as to reduce run-time by avoiding a double indirection and whether there are mutex locks and where these does not really matter to the remainder of this discussion. It is, however, assumed that the implementer chooses an efficient implementation of the std::locale.

It is worth noting that the Standard definition of std::use_facet() and std::has_facet() differ from the CD2 (Committee Draft 2 – pre-IS) version quite significantly. If a facet is not found in a locale object, it is not available for this locale. In CD2, the global locale object was searched for a facet not present a given locale object. The Standard version can be more efficient - to determine whether a facet is available for a given locale object, a simple array lookup is sufficient. Basically, the functions std::use_facet() and std::has_facet() could look something like:

```cpp
extern std::locale::facet dummy;

template <typename F>
bool has_facet(std::locale const& loc) {
    return loc.rep->facets[F::id::index] == &dummy;
}

template <typename F>
F const& use_facet(std::locale const& loc) {
    return dynamic_cast<F const&>(*loc.rep->facets[Facet::id::index]);
}
```

This version of the functions is tuned for speed. A simple array lookup, together with the necessary dynamic_cast<> is used to obtain a facet. Since this implies that there is a slot for each facet possibly used by the program in the array, it may be somewhat wasteful with respect to memory. Other techniques might check the size of the array first or store id/facet pairs. In extreme cases, it is possible to locate the correct facet using dynamic_cast<> and storing only those facets that are actually available in the given locale.

### 3.2.2 Reducing Executable Size

Linking unused code into an executable can have a significant impact on the executable size. Thus, it is best to avoid having unused code in the executable.
program. One source of unused code results from trivial implementations. The default facet `std::locale::classic()` includes a certain set of facets as described in IS-22.1.1.1.1¶2. It is tempting to implement the creation of the corresponding locale with a straightforward approach, namely explicitly registering the listed facets:

```cpp
std::locale const& std::locale::classic() {
    static std::locale object;
    static bool unitialized = true;

    if (unitialized) {
        object.intern_register(new collate<char>);
        object.intern_register(new collate<wchar_t>);
        // ...
    }
    return object;
}
```

This approach however can result in a very large executable, as it drags in all facets listed in the table. The advantage of this approach is that a relatively simple implementation of the various locale operations is possible. An alternative is to include only those facets that are really used. A simple approach for doing this is to provide specialized versions of `use_facet()` and `has_facet()` which might be appropriate for `has_facet()` anyway, for example:

```cpp
template <typename F> struct facet_aux {
    static F const& use_facet(locale const& l) {
        return dynamic_cast<F const&>(*l.rep
          ->facets[Facet::id::index]);
    }
    static bool has_facet(locale const& l) { return l.rep->facets[F::id::index] == &dummy; }
};
template <> struct facet_aux<char> { static ctype<char> const& use_facet(locale const& l) { try {
        return dynamic_cast<ctype<char> const&>(*l.rep
          ->facets[Facet::id::index]);
    } catch (bad_cast const&) { locale::facet* f = l.intern_register(new ctype<char>);
        return dynamic_cast<ctype<char> const&>(*f); }
    }
    static bool has_facet(locale const& l) { return true; }
};
// similarly for the other facets
template <typename F>
F const& use_facet(locale const& l) { return facet_aux<F>::use_facet(l); }
template <typename F>
bool has_facet(locale const& l) { return facet_aux<F>::has_facet(l); }
```

Again, this is just one example of many possible implementations for what is basically a recurring theme. A facet is created only if it is really referenced from the program. This particular approach is suitable in implementations where exceptions
cause a run-time overhead only if they are indeed thrown because like the normal
evolution path, if the lookup of the facet is successful, it is not burdened by the extra
code used to initialise the facet. Although the above code seems to imply that
struct facet_aux has to be specialized for all required facets individually, this need
not be the case. By using an additional template argument, it is possible to use partial
specialization together with some tagging mechanism, to determine whether the facet
should be created on the fly if it is not yet present.

Different implementations of the lazy facet initialisation include the use of static
initialisers to register used facets. In this case, the specialised versions of the function
use_facet() would be placed into individual object files together with an object
whose static initialisation registers the corresponding facet. This approach implies
however, that the function use_facet() is implemented out-of-line, possibly causing
unnecessary overhead both in terms of run-time and executable size.

The next source of unused code is the combination of several related aspects in just
one facet due to the use of virtual functions. Normally, instantiation of a class
containing virtual functions requires that the code for all virtual functions be present,
even if they are unused. This can be relatively expensive as for example, in the case
of the facet dealing with numeric formatting. Even if only the integer formatting
functions are used, the typically bigger code for the floating point formatting gets
dragged in just to resolve the symbols referenced from the "virtual function table".

A better approach to avoid linking of unused virtual functions involves changing the
compiler such that it generates appropriate symbols, allowing the linker to determine
whether a virtual function is really called. If it is, the reference from the virtual
function table is resolved; otherwise, there is no need to resolve it because it will
never be called anyway.

Note (Deitmar): Details for this are described elsewhere (currently, I don't have a
reference I can point to but I know that Nathan Myers has dealt with
this for gcc).

For the Standard facets however, there is a “Poor Man's” alternative that comes close
to having the same effect. The idea is to provide a stub implementation for the virtual
functions, which is placed in the library such that it is searched fairly late. The real
implementation is placed before the stub implementation in the same object file along
with the implementation of the forwarding function. Since a use of the virtual
function has to go through the forwarding function, this symbol is also un-referenced,
and resolving it brings in the correct implementation of the virtual function.

Unfortunately, it is not totally true that the virtual function can only be called through
the forwarding function. A class deriving from the facet can directly call the virtual
function because these are protected rather than private. Thus, it is still necessary
to drag in the whole implementation if there is a derived facet. To avoid this, another
implementation can be placed in the same object file as the constructors of the facet,
which can be called using a hidden constructor for the automatic instantiation.
Although it is possible to get these things to work with typical linkers, a modified
compiler and linker provide a much-preferred solution, which if often outside of the
scope of the library implementers.
Basically, most of the normally visible code bloat can be removed using these two techniques, i.e. by including only used facets and avoiding the inclusion of unused virtual functions. Some of the approaches described in the other sections can also result in a reduction of executable size, but the focus of those optimisations is on a different aspect of the problem. Also, the reduction in code size for the other approaches is not as significant.

3.2.3 Pre-Processing for Facets

Once the executable size is reduced, the next observation is that the operations tend to be slow. Take numeric formatting as an example: to produce the formatted output of a number, three different facets are involved:

- `num_put` which does the actual formatting; i.e. determining which digits and symbols are there; doing padding when necessary; etc.
- `numpunct` which provides details about local conventions, such as the need to put in thousands separators; which character to use as a decimal point; etc.
- `ctype` which transforms the characters produced internally by `num_put`, into the appropriate "wide" characters.

Each of the `ctype` or `numpunct` functions called is basically a virtual function. A virtual function call can be an expensive way to determine whether a certain character is a decimal point; or to transform a character between a narrow and wide representation. Thus, it is necessary to avoid these calls wherever possible for maximum efficiency.

At first examination there does not appear to be much room for improvement. However, on closer inspection, it turns out that the Standard does not mandate calls to `numpunct` or `ctype` for each piece of information. If the `num_put` facet has widened a character already, or knows which decimal point to use, it is not required to call the corresponding functions. This can be taken a step further. When creating a locale object, certain data can be cached using for example, an auxiliary hidden facet. Rather than going through virtual functions over and over again, the required data is simply stored in an appropriate data structure.

For example, the cache for the numeric formatting might consist of a character translation table resulting from widening all digit and symbol characters during the initial locale set-up. This translation table might also contain the decimal point and thousands separator - combining data obtained from two different facets into just one table. Taking it another step further, the cache might be set up to use two different functions depending on whether thousands separators are used according to the `numpunct` facet or not. Some pre-processing might also improve the performance of parsing strings like the Boolean values if the `std::ios_base::boolalpha` flag is set.

Although there are many details to be handled like for example, distinguishing between normal and cache facets when creating a new locale object, the effect of using a cache can be fairly significant. It is important that the cache facets are not generally shared between locale representations. To share the cache, it has to be verified that all facets contributing to the cached data are identical in each of the
corresponding locales. Also, certain things like, the use of two different functions for
formatting with or without thousands separators only work if the default facet is used.

3.2.4 Compile-Time Decoupling

It may appear strange to talk about improving compile-times when discussing the
efficiency of locales but there are good reasons for this. First of all, compile-time is
just another concern for performance efficiency, and it should be minimized where
possible. More important to this paper however, is that some of the techniques
presented below, rely on certain aspects that are related to the compilation process.

The first thing that improves compile-time is the liberal use of declarations, avoiding
definitions wherever possible. A Standard header may be required to include other
headers that provide a needed definition (§17.4.4.1), however, this does not apply to declarations. As a consequence, a header need not be included just because it
defines a type which is used only as return or argument type where a declaration is
sufficient. Likewise, a declaration is sufficient if only a pointer or a class is used as a
member.

Looking at the members \texttt{imbue()} and \texttt{getloc()} of the class \texttt{std::ios\_base}, it
would seem that an object of this type is required to include <\texttt{locale}> simply for the
definition of \texttt{std::locale}, because apparently, an \texttt{std::ios\_base} object stores an
object of this type in a member variable. This is, not required! Instead,
\texttt{std::ios\_base} could store the pointer to the locale's internal representation and
construct an \texttt{std::locale} object on the fly. Thus, there is no need for the header
<\texttt{ios}> to include the header <\texttt{locale}>. The header <\texttt{locale}> will be used elsewhere
with the implementation of the \texttt{std::ios\_base} class but that is a completely different
issue.

Why does it matter? Current compilers lacking support for the \texttt{export} keyword
require the implementation of the template members of the other stream classes in the
headers anyway and the implementation of these classes will need the definitions
from <\texttt{locale}> - won't they? It is true that some definitions of the template members
will indeed require definitions from the header <\texttt{locale}>. However, this does not imply that the implementation of the template members is required to reside in the
header files - a simple alternative is to explicitly instantiate the corresponding
templates in suitable object files.

Explicit instantiation obviously works for the template arguments mentioned in the
Standard, for example, explicit specialisation of \texttt{std::basic\_ios<char>} and
\texttt{std::basic\_ios<wchar\_t>} works for the \texttt{class template} \texttt{std::basic\_ios}. But
what happens when the user tries some other type as the character representation, or a
different type for the character traits? Since the implementation is not inline but
requires explicit instantiation, it cannot always be present in the Standard library
shipped with the compiler. The usual approach to this problem is to use the \texttt{export}
keyword but in the absence of this, an entirely different approach is necessary. One
such approach is to instruct the user on how to instantiate the corresponding classes
using for example, some environment specific implementation file, and suitable
compiler switches. For instance, instantiating the `Iostream` classes for the character
type `mychar` and the traits type `mytraits` might look something like:

```cpp
    c++ -o io-inst-mychar-mytraits.o io-inst.cpp \
        -DcharT=mychar -Dtraits=mytraits -Dinclude="mychar.hpp"
```

Using such an approach causes some trouble to the user and more work for the
implementor, which seems to be a fairly high price to pay for a reduction in
dependencies, and a speed up of compile-time. But note that the improvement in
compile-time is typically significant when compiling with optimisations enabled. The
reason for this is simple: with all those inline functions, the compiler causes huge
chunks of codes to be passed on to the optimiser which then has to work extra hard to
improve them. Bigger chunks provide better optimisation possibilities, but they also
cause significantly longer compile-times due to the non-linear increase in the
complexity of the optimisation step as the size of the chunks increases. Furthermore,
the object files written and later processed by the linker are much bigger when all
used instantiations are present in each object file. This can also impact the executable
size, because certain code may be present multiple times embedded in different inline
functions which are different but which have some code from just one other function
in common.

Another reason for having the `Iostream` and `Locale` functions in a separate place, is
that it is possible to tell from the undefined symbols, which features are used in a
program, and which are not. This information can then be used by a smart-linker to
determine which particular implementation of a function is most suitable for a given
application.

### 3.2.5 Smart Linking

The discussion above already addresses how to avoid unused code using a slightly
non-trivial implementation of locales and virtual functions. It does not address how to
avoid unnecessary code. The term “unnecessary code” refers to code that is actually
executed, but which does not really have any effect. For example, the code for
padding formatted results does not have an effect if the `width()` is never set to a non-zero
value. Similarly, there is no need to go through the virtual functions of the
various facets, if only the default locale ever used. As for all other aspects of C++, it
is reasonable to avoid the costs in code size and performance when the corresponding
feature is not used.
The basic idea for coping with this is to provide multiple implementations of the same function that avoids unnecessary overheads where possible. Since writing multiple implementations of the same function can easily become a maintenance nightmare, it makes sense to write one implementation, which is configured at compile-time to handle different situations. For example, a function for numeric formatting that optionally avoids the code for padding might look like this:

```cpp
template <typename cT, typename OutIt>
num_put<cT, OutIt>::do_put(OutIt it, ios_base& fmt,
       cT fill, long v) const
{
    char buffer[some_suitable_size];
    char* end = getFormatted(fmt, v);
    if (need_padding && fmt.width() > 0)
        return put_padded(it, fmt, fill, buffer);
    else
        return put(it, fmt, buffer);
}
```

The value `need_padding` is a constant Boolean which is set to `false` if the compilation is configured to avoid padding code. With a clever compiler (normally requiring optimisation to be enabled) any reference to `put_padded()` is avoided, as is the check for whether the `width()` is greater than zero. The library would just supply two versions of this function and the smart-linker would need to choose the right one.

To choose the right one, the linker has to be told under what circumstances it should use the one avoiding the padding, i.e. the one where `need_padding` is set to `false`. A simple analysis shows that the only possibility for `width()` being non-zero is the use of the `std::ios_base::width()` function with a parameter. The library does not set a non-zero variable, and hence the simpler version can be used if `std::ios_base::width()` is never referenced from user code.

The example of padding is pretty simple. Other cases are more complex but still manageable. Another issue worth considering is whether the `Locales` library has to be used or if it is possible to provide the functionality directly, possibly using functions that are shared internally between the `Locales` and the `ISTREAMS` library. That is, if only the default locale is used, the `ISTREAMS` functions can call the formatting functions directly, bypassing the retrieval of the corresponding facet and associated virtual function call - moreover, bypassing any code related to locales - avoiding the need to drag in the corresponding locale maintenance code.

The analysis necessary to check if only the default locale is used is more complex however. The simple test is to check for the locale's constructor. If only the default and copy constructors are used, then only the default locale is used because one of the other constructors is required to even create a different locale object. Even then, if another locale object is constructed, it is not necessarily used with the `ISTREAMS`. Only if the global locale is ever changed, or if `std::ios_base::imbue()`, `std::basic_ios<...>::imbue()`, or `std::basic_streambuf<...>::imbue()` are ever called, can the streams be affected by the non-default locale object. Although it this is somewhat more complex to determine, it is still manageable. There are other things which might be exploited too, for example, whether the streams have to deal with exceptions in the input or output functions (this depends on the stream buffer and
locales possibly used); whether calling of callback functions is needed (only if callbacks are ever registered, is this necessary); etc.

The approach taken by the linker to decide which functionality is used by the application requires using a set of “rules” provided by the library implementor to exclude functions. It is important to base these rules only on the application code to avoid unnecessary restrictions imposed by unused library code. This however results in more rules and rules that are more complex. To determine which functionality is used by the application code, the unresolved symbols referenced by the application code are examined. This requires that any function used as a “rule” is indeed unresolved and results in the corresponding functions being non-inline.

There are basically three problems with this approach:

- The maintenance of the implementation becomes more complex because extra work is necessary. This can be reduced to a more acceptable level by relying on clever compilers eliminating code for branches that the compiler can determine, are never used.
- The analysis of the conditions under which code can be avoided is sometimes non-trivial. Also, the conditions have to be made available to the linker, which introduces another potential cause of error.
- Even simple functions used to exclude a simple implementation of the function std::ios_base::width() cannot be inline. This might result in less efficient and sometimes even bigger code (for simple functions the cost of calling the function can be bigger than the actual function). See 3.2.7 for an approach for avoiding this problem.

The same approach can be beneficial to other libraries, and to other areas of the Standard C++ library than just the Iostreams and Locales library. In general, it can simplify the library interface by removing similar functions applicable in different situations, while still retaining the same efficiency. It is however, not always applicable in such situations and should be used carefully where appropriate.

3.2.6 Object Organization

A typical approach to organise a class is to have member variables for all attributes to be maintained. This may seem to be a natural approach, but it can result in a bigger footprint than necessary. For example, in an application where the width() is never changed, there is no need to actually store the width(). When looking at the Iostreams library, it turns out that each std::basic_ios object might store a relatively large amount of data to provide functionality that many C++ programmers using Iostreams are not even aware of, for example:

- A set of formatting flags is stored in an std::ios_base::fmtflags object.
- Formatting parameters like the width() and the precision() are stored in std::streamsize objects.
- An std::locale object (or some suitable reference to its internal representation) is stored.
The `pword()` and `iword()` lists are stored.

- A list of callbacks is stored.

- The error flags and exception flags are stored in objects of type `std::ios_base::iostate`. Since these basically consist of just three bits, they may be folded into just one word.

- The fill character used for padding is stored.

- A pointer to the used stream buffer is stored.

- A pointer to the `tie()`ed `std::basic_ostream` is stored.

This results in at least eight extra 32-bit words, even when folding multiple data into just one 32-bit word where possible (the formatting flags, the state and exception flags, and the fill character can fit into 32-bits for the character type `char`). These are 32 bytes for every stream object even if there is just one stream, for example, `std::cout` which never uses a different precision, width (and thus no fill character), or locale; probably does not set up special formatting flags using the `pword()` or `iword()` facilities; almost certainly does not use callbacks, and is not `tie()`ed to anything. It might get away with being an object needing no members at all, and in such a case - which is not very unlikely in an embedded application - by just sending string literals somewhere!

A different organization could be the use of an array of unions and using the `pword()`/`iword()` mechanism to store the data. Each of the pieces of data listed above is given an index of its position in an array of unions (possibly, several pieces can share just one union like they shared just one word in the conventional setting). Only the `pword()`/`iword()` pieces would not be stored in this array because they are required to access the array. A feature never accessed does not get an index and thus does not require any space in the array. The only complication is how to deal with the `std::locale`, because it is the only non-POD data. This can be handled using for example, a pointer to the locale's internal representation.

Depending on the exact organization, the approach will show different run-time characteristics. For example, the easiest approach for assigning indices is to do it on the fly when the corresponding data is initialised or first accessed. This may however, result in arrays which are smaller than the maximum index and thus the access to the array has to be bounds-checked (in case of an out-of-bound access, the array might have to be increased; it is only an error to access the corresponding element if the index is bigger than the biggest index provided so far by `std::ios_base::xalloc()`).

An alternative is to determine the maximum number of slots used by the Standard library at link time or at start-up time before the first stream object is initialised. In this case, there would be no need to check for out-of-bound access to the `Iostream` features. However, this initialisation is more complex.

A similar approach can be applied to the `std::locale` objects.
3.2.7 Library Recompilation

So far, the techniques described assume that the application is linked to a pre-packaged library implementation. Although the library might contain different variations on some functions, it is still pre-packaged (the templates possibly instantiated by the user can also be considered to be pre-packaged). This is however, often not a necessary assumption! If the library code is available, the Standard library can also be recompiled.

This leads to the “two phase” building of an application; where in a first phase, the application is compiled against a "normal", fully-fledged implementation. The resulting object files are automatically analysed for features actually used, by looking at the unresolved references. The result of this analysis is some configuration information (possible a file), which uses conditional compilation to remove all unused features from the Standard library; in particular, removing unused member variables and unnecessary code. In the second phase, this configuration information is then used to recompile the Standard library and the application code for the final program.

This approach does not suffer from drawbacks due to dynamic determination of what are effectively static features. For example, if it is known at compile-time which \texttt{iostream} features are used, the stream objects can be organised to include members for exactly those features. Thus, it is not necessary to use a lookup in a dynamically allocated array, possibly using a dynamically assigned index. Also, in the final compilation phase, it is possible to inline functions that were not previously inlined (in order to produce the unresolved symbol references).

3.3 ROMability

For the purposes of this paper, the terms “ROMable” and “ROMability” refer to entities that are appropriate for placement in “Read-Only Memory” and to the process of placing entities into Read-Only-Memory so as to enhance the performance of programs written in C++.

There are two principal domains that benefit from this process:

- Embedded programs which have constraints on available memory, where code and data must be stored in physical ROM whenever possible.
- Modern operating systems which support the sharing of code and data among many instances of a program, or among several programs sharing invariant code and data.

The subject of ROMability therefore has performance application to all programs, where immutable aspects of the program can be placed in a shared and “Read-Only” space. On hosted systems, Read-Only is enforced by the memory manager, while in embedded systems, it is enforced by the physical nature of ROM devices.

For embedded programs where memory requirements are scarce, it is critical that compilers identify strictly ROMable objects and allocate only ROM area for them. For hosted systems, the requirement to share ROMable information is not as critical, but there are inevitable performance advantages to hosted programs as memory
footprint and the time it takes to load a program can be greatly reduced. All the techniques described in this section will benefit such programs.

### 3.3.1 ROMable Objects

Most constant information is ROMable. Obvious candidates for ROMability are objects of static extent that are declared `const`, and which have constant initialisers; but there are several other significant candidates too.

Objects which are not declared `const` can be modified, and are consequently not ROMable. But these objects may have constant initialisers, and those initialisers may be ROMable. This paper considers those entities in a program that are obviously ROMable such as global `const` objects; entities that are generated by the compilation system to support functionality such a `switch-statements`; and also places where ROMability can be applied to intermediate entities which are not so obvious.

#### 3.3.1.1 User-defined objects

Objects declared `const` that are initialised with constant expressions. Examples:

- An aggregate (§IS-18.5.1) object with static storage duration (§IS-3.7.1) whose initialisers are all constants:
  ```
  static const int tab[] = {1,2,3};
  ```

- Objects of scalar type with external linkage:
  A const-qualified object of scalar type has internal (§IS-7.1.5.1) or no (§IS-3.2.5) linkage and thus can usually be treated as a compile-time constant, i.e. object data areas are not allocated, even in ROM. For example:
  ```
  const int tabsize = 48
  double table[tabsize];    // table has space for 48 doubles
  ```

  However, if an object of scalar type is used for initialisation or assignment of pointer or reference variables, it has internal linkage and is ROMable. For example:
  ```
  extern const int a = 1;    // external linkage
  const int b = 1;           // internal linkage
  const int *c = &b;         // variable b should be allocated
  const int tbsize = 256;    // it is expected that tbsize is not
  char ctb[tbsize];          // allocated at run-time
  ```

- String literals:
  An ordinary string literal has the type “array of `const char``” (§IS-2.13.4), and so they are ROMable. A string literal used as the initialiser of a character array if ROMable, but if the variable to be initialised is not a const-qualified array of `char`, then the variable being initialised is not ROMable:
  ```
  const char *str1 = "abc";    // both str1 and "abc" are ROMable
  char str2[] = "def";         // str2 is not ROMable
  ```
A compiler may achieve further space savings by sharing the representation of string literals in ROM. For example:

```c
const char* str1 = "abc"; // only one copy of "abc" needs
const char* str2 = "abc"; // to exist, and it is ROMable
```

Yet further possibilities for space saving exists if a string literal is identical to the trailing portion of a larger string literal, as only the larger string literal is necessary, as the smaller one can reference the common sub-string of the larger. For example:

```c
const char* str1 = "Hello World";
const char* str2 = "World";

// Could be considered to be implicitly:
const char* str1 = "Hello World";
const char* str2 = str1 + 6;
```

### 3.3.1.2 Compiler-generated objects

- Jump tables for switch statements:
  
  If a jump table is generated to implement switch statement, the table is ROMable, since it consists of a fixed number of constants known at compile-time.

- Virtual function tables:
  
  Virtual function tables of a class are usually ROMable.

  **Note:** For some implementations, the virtual function tables may not be ROMable where dynamic linking is involved, and the virtual function tables are in a shared library.

  **Note also:** It may be appropriate to discuss flash cards here, and how they can introduce code into a system.

- Type identification tables:
  
  When a table is generated to identify RTTI types, the table is usually ROMable.

  **Note:** For some implementations, the type identification tables may not be ROMable where dynamic linking is involved, and the type identification tables are in a shared library.

- Exception tables:
  
  When exception handling is implemented using a static table, the table is usually ROMable.

  **Note:** For some implementations, the exception tables may not be ROMable where dynamic linking is involved, and the exception tables are in a shared library.
• Reference to constants:

If a constant expression is specified as the initialiser for a const-qualified reference, a temporary object is generated (§15.8.5.3).

This temporary object is ROMable, for example:

```cpp
// The declaration:
const double & a = 2.0;

// May be represented as:
static const double tmp = 2.0; // 'tmp' is ROMable
const double & b = tmp;
```

• Initialisers for aggregate objects with automatic storage duration:

If all the initialisers for an aggregate object that has automatic storage duration are constant expressions, a temporary object that has the value of the constant expressions and a code that copies the value of the temporary object to the aggregate object may be generated. This temporary object ROMable, for example:

```cpp
struct A {
    int a;
    int b;
    int c;
};
void test() {
    A a = {1,2,3};
}

// May be interpreted as:
void test () {
    static const A tmp = {1,2,3}; // 'tmp' is ROMable
    A b = tmp;
}
```

Thus, the instruction code for initialising the aggregate object can be replaced by a simple bitwise copy, saving both code space and execution time.

• Constants created during code generation:

Some literals such as integer literals, floating point literals and addresses can be implemented as either instruction code or data. If they are represented as data, then these objects are ROMable. For example:

```cpp
void test() {
    double a;
    a += 1.0;
}

// May be interpreted as:
void test () {
    static const double tmp = 1.0; // 'tmp' is ROMable
    double a;
    a += tmp;
}
```
3.3.2 Constructors and ROMable Objects

In general, objects of classes with constructors must be dynamically initialised. However, in some cases the initialisation could be performed if static analyses of the constructors resulted in constant values being used. In this case, the object could be ROMable. Similar analyses would need to be performed on the destructor.

```cpp
class A {
    int a;
    public:
    A(int v) : a(v) { }
    const A tab[2] = {1,2};
}
```

**Editor’s Note:** If sufficient analyses reveals that the object eventually gets a particular value, and the program cannot detect whether it acquired that value by constant or dynamic means, then it is quite legitimate for it to be ROMable\(^2\).

Furthermore, even if it is not a `const` object, the initialisation “pattern” may be ROMable, and bitwise copied to the object when it is initialised. For example:

```cpp
class X {
    int a;
    char* p;
    public:
    X ()
    { a (7 )
        { std::cout << "Hello World" << std::endl;
        p = "Hi"; }
    }
    A not_const;
}
```

In this case, all objects are initialised to a constant value (the pair `{7,"Hi"}`). This constant initial value is ROMable, and the constructor could perform a bitwise copy of that constant value and the calls to the IOSTream library.

3.4 Hard Real-Time Considerations

For most embedded systems, only a very small part of the software is really real-time critical. But for that part of the system, it is important to exactly determine the time a specific piece of software needs to run. Unfortunately, this is not an easy analysis to do for modern computer architectures using multiple pipelines and different types of caches. Nevertheless, for a lot of code sequences it is still quite straightforward to do a worst-case analysis.

**Note (Detlef):** Bjarne’s Phrase goes here.

**Editor’s Note:** What is “Bjarne’s Phrase”?\(^1\)

---

\(^2\) This is an optimisation, and is subject to the so-called “as if rule” (§1S-1.9\(^1\))
This statement also holds for C++. Here is a short description of several C++ features and their time predictability.

3.4.1 C++ Features for which an Accurate Timing Analysis is Easy

3.4.1.1 Templates
As pointed out in detail in 2.5, there is no real-time relevant overhead for calling template functions or member functions of class templates. On the contrary, templates often allow for better inlining and therefore reduce the overhead of the function call.

If the function is a virtual function, the normal rules for virtual functions apply.

3.4.1.2 Inheritance
Converting a pointer to a derived class to a pointer to base-class\(^{24}\) will not introduce any run-time overhead in most implementations (§2.3). If there is an overhead (very few implementations), it is a fixed number of machine instructions (typically one) and can be easily tested with a test program. Being a fixed overhead, this overhead does not depend on the deepness of the derivation.

3.4.1.2.1 Multiple-Inheritance
Converting a pointer to a derived class to a pointer to base class might introduce run-time overhead (§2.3.5). This overhead is a fixed number of machine instructions (typically one).

3.4.1.2.2 Virtual-Inheritance
Converting a pointer to a derived class to a pointer to a virtual base class will introduce run-time overhead in most implementations (§2.3.6). This overhead is typically a fixed number of machine instructions.

3.4.1.3 Virtual Functions
Calling a virtual function often does not produce any run-time overhead (§2.3.3). If it does, it will typically be a fixed number of machine instructions.

3.4.2 C++ Features, for which Real-Time Analysis is More Complex
The following features are often considered to be prohibitively slow for hard real-time code sequences. But this is not always true. For one, the run-time overhead of these features is often quite small, and on the other-hand even in the real-time parts of your program, you might have quite a number of CPU cycles to spend. And if you have a complex job to do in your real-time code, a clean structure that allows for an easier overall timing analysis is often better than a hand-optimised but complicated code – as long as the former is fast enough. The hand-optimised code might run faster but is in most cases more difficult to analyse correctly. And the features mentioned below often allow for clearer designs.

---

\(^{24}\) Such a conversion is also necessary if a function is called for a derived-class object that is implemented in a base-class.
3.4.2.1 Dynamic Casts
In most implementations, dynamic casts from a pointer (or reference) to base-class to
pointer (or reference) to derived-class (i.e. a downcast) will produce an overhead that
is not fixed but depends on the details of the implementation and there is no general
rule to test the worst case.

The same is true for cross-casts (§2.2).

As an alternate option to using dynamic-casts, you should consider the typeid
operator. If you know your target’s dynamic type exactly, this is a much cheaper way
to check for it.

3.4.2.2 Dynamic Memory Allocation
Dynamic memory allocation has in typical implementations a run-time overhead that
is not easy to analyse. In most cases, for the purpose of real-time analysis it is
appropriate to assume dynamic memory allocation (and also memory de-allocation) to
be non-deterministic.

The most obvious way to avoid dynamic memory allocation is to pre-allocate the
memory – either statically at compile- (or more correctly link-) time or during the
general set-up-phase of your system. If you want to defer the initialisation, you can
pre-allocate raw memory and initialise it later using placement new.

If you really need to do dynamic memory allocation in your real-time code, you need
to use an implementation for which you know all the implementation details. The
best way to know all the implementation details is to write your own memory
allocation mechanism. This is easily done in C++ by overriding operator new in
your own class (or globally) or by providing an allocator argument in standard library
containers.

But in all cases, if you use dynamic memory allocation you need to consider the case
when no more memory is available.

3.4.2.3 Exceptions
Enabling exceptions for compilation may introduce overhead on each function call in
your code (§2.4). In general, it is not so difficult to analyse the overhead of exception
handling as long as you don't throw exception. But you should only enable exception
handling for real-time critical programs if you really use exceptions, and therefore a
complete analysis must always include the throwing of an exception, and this analysis
will always be implementation dependent. On the other hand, the requirement to act
within a deterministic time might loosen in the case of an exception (e.g. you don’t
need to handle any more input from a device when a connection broke down).
An overview of alternatives for exception handling is given in [Note (Detlef): Insert Bjarne's new section]. But as shown there, all options have their run-time costs, and throwing exceptions might still be the best way to deal with exceptional cases. And as long as you don’t throw a long way (i.e. if you only leave very few functions in your throw), it might be even cheap in run-time.

| Note (Detlef): | Is this list complete? |

### 3.4.3 Testing Timing

For those features that compile to a fixed number of machine instructions, the number and nature of these instructions (and therefore an exact worst-case timing) can be tested with a simple program that includes just this specific feature and then looking at the created code. In general, for those simple cases, optimisation should not make a difference. But e.g. if a virtual function call can be resolved to a static function call at compile-time, the overhead of the virtual function call will not show up in the code. So, you need to make sure that you really test what you want to test.

For the more complex cases, testing the timing is not so easy. Compiler optimisation can make a big difference, and a simple test case might produce completely different code than the real production code. To test those cases, you must really know the details for your specific implementation. Given this information, you can normally produce test programs that produce code from which you can correctly derive the timing information you need.
4 Embedded Systems – Special Needs

As the C language has matured over the years, various extensions for accessing basic I/O-Hardware registers have been added to address deficiencies in the language. Today almost all C compilers for freestanding environments and embedded systems support some method of direct access to I/O-Hardware registers from the C source level. However, these extensions have not been consistent across dialects. As a growing number of C++ compiler vendors are now entering the same market, the same I/O driver portability problems become apparent for C++.

As a simple portability goal, the driver source code for some given I/O-Hardware should be portable to all processor architectures where the hardware itself can be connected. Ideally, it should be possible to compile source code that operates directly on I/O-Hardware registers with different compiler implementations for different platforms and get the same logical behaviour at run-time.

Obviously standard interface definitions written in the common subset of C and C++ would have the widest potential audience, since they would be readable by compilers for both languages. But the additional abstraction mechanisms of C++, such as classes and templates, are useful in writing code at the hardware access layer. They allow the encapsulation of features into classes, providing type safety along with maximum efficiency through the use of templates.

Nevertheless, it is an important goal to provide an interface that allows device driver implementers to write code that compiles equally under C and C++ compilers. Therefore, this report specifies two interfaces: one using the common subset and a second using modern C++ constructs. Implementers of the common subset-style interface might use functions or inline functions, or might decide that function-like macros or intrinsic functions better serve their objectives.

A proposed interface for addressing I/O-Hardware in the C language is described in:

**Technical Report ISO/IEC WDTR 18037**

"Extensions for the programming language C to support embedded processors"

This interface is referred to as iohw in this report. It includes in this report for the convenience of the reader. If the description of iohw in this report differs from the description in ISO/IEC WDTR 18037, the description there takes precedence. iohw is also used to refer to both the C and C++ interface where they share common characteristics. In parallel with that document, the interfaces using the common subset of C and C++ are contained in a header named <iohw.h>.

Although iohw is based on C macros, the C++ language provides features which make it possible to create efficient and flexible implementations of this interface, while maintaining I/O driver source code portability. The C++ interfaces are contained in a header named <hardware>, and their symbols are placed in the namespace std::hardware.
The name is deliberately different, as it is the intention that <hardware> provides similar functionality to <iohw.h>, but through a different implementation, just as <iostream> provides parallel functionality with <stdio.h> through different interfaces and implementation. There is no header <ciohw> specified, as that name would imply (by analogy with other standard library headers) that the C++ interfaces were identical to those in <iohw.h> but placed inside a namespace.

| Editor’s Note: | I don’t agree. In C++ there is no header <stdio.h>, rather there is only <cstdio>. I think that the same process should apply to <iohw.h>. |

This report provides

- a general introduction and overview to the iohw interface (§4.1),
- a copy of the C interface (§4.2.1),
- the description of the C++ interface (§4.2.2),
- usage guidelines for the C++ interface (§4.3),
- general implementation guidelines for both interfaces (§4.3.1)
- implementation guidelines for the C++ interface (§A.7)
- implementation guidelines and example for the C interface on top of the C++ interface (§A.8)
- an example of a real world device driver using the C++ interface (§Appendix C)

### 4.1 Introduction to I/O-Hardware Addressing

| Note (Detlef): | This is essentially the old 4.1.3 and 4.2. |

The purpose of the iohw access functions defined in the iohw header file is to promote portability of iohw driver source code across different execution environments.

#### 4.1.1 Basic Standardisation Objectives

A standardisation method for basic I/O-Hardware addressing must be able to fulfil three requirements at the same time:

- A standardised interface must not prevent compilers from producing machine code that has no additional overhead compared to code produced by existing proprietary solutions. This requirement is essential in order to get widespread acceptance from the embedded programming community.

- The I/O driver source code modules should be completely portable to any processor system without any modifications to the driver source code being required [i.e. the syntax should promote I/O driver source code portability across different execution environments].

- A standardised interface should provide an “encapsulation” of the underlying access mechanisms to allow different access methods, different processor
architectures, and different bus systems to be used with the same I/O driver source code \[i.e. the standardisation method should separate the characteristics of the I/O register itself from the characteristics of the underlying execution environment (processor architecture, bus system, addresses, alignment, endian, etc.).\]

### 4.1.2 Overview and Principles

The `iohw` access functions create a simple and platform independent interface between I/O driver source code and the underlying access methods used when addressing the hardware registers on a given platform.

The primary purpose of the interface is to separate characteristics which are portable and specific for a given hardware register, for instance the register bit width; from characteristics which are related to a specific execution environment, such as the hardware register address; processor bus type and endian; device\(^{25}\) bus size and endianness, address interleave; compiler access method; etc. Use of this separation principle enables I/O driver source code itself to be portable to all platforms where the hardware registers can be connected.

In the driver source code, a hardware register must always be referred to using a symbolic name. The symbolic name must refer to a complete definition of the access method used with the given register. A standardised I/O syntax approach creates a conceptually simple model for hardware registers:

\[
\text{symbolic name for hardware register} \Leftrightarrow \text{complete definition of the access method}
\]

When porting the driver source code to a new platform, only the definition of the access method (definition of the symbolic name) needs to be updated.

### 4.1.3 The Abstract Model

The standardisation of basic `iohw` addressing is based on a three layer abstract model:

<table>
<thead>
<tr>
<th>The users portable source code</th>
</tr>
</thead>
<tbody>
<tr>
<td>The users I/O register definitions</td>
</tr>
<tr>
<td>The vendors <code>iohw</code> implementation</td>
</tr>
</tbody>
</table>

The top layer contains the driver source code written by the compiler user. The source code in this layer is fully portable to any platform where the hardware device can be connected. This code may only access hardware registers via the standardized functions described in this section. Each hardware register must be identified using a symbolic name.

The bottom layer is the compiler vendors implementation of `iohw`. It provides prototypes for the functions defined in this section and specifies the various access methods supported by the given processor and platform architecture (*access

\(^{25}\) In this document, the term device is used to mean either a discrete I/O chip or an I/O function block in a single chip processor system. The data bus width has significance to the access method used for the I/O device.
methods” refers to the various ways of connecting and addressing hardware registers or hardware devices in the given processor architecture).

A.2 contains some general considerations that should be addressed when a compiler vendor implements the iohw functionality.

The middle layer contains the user’s specification of the symbolic hardware register names used by the source code in the top layer. This layer associates the symbolic names with access-specifications for a specific hardware register on the given platform. The syntax notation and access specification parameters used in this layer are specific to the platform architecture and are defined by the compiler vendor in the iohw header. The user must update these hardware register access specifications when the hardware driver source code is ported to a different platform.

A.3 proposes a generic C++ syntax for hardware register access specifications. Using a general syntax in this layer may extend portability to include user’s hardware register specifications, so it can be used with different compiler implementations for the same platform.

4.1.3.1 The Module Set

A typical device driver operates with a minimum of three modules, one for each of the abstraction layers. For example, it is convenient to locate all hardware register name definitions in a separate header file (called “hw_ta.h” in this example):

1. Device driver module
   - The I/O driver source code
   - Portable across compilers and platforms
   - Includes <iohw.h> and "hw_ta.h"

2. Interface header <iohw.h>
   - Defines I/O functions and access methods
   - Typically specific for a given compiler
   - Implemented by the compiler vendor

3. "hw_ta.h"
   - Defines symbolic hardware register names and their corresponding access methods
   - Specific to the execution environment
   - Implemented and maintained by the programmer

And might be used as follows (in a common subset of C and C++):

```c
#include <iohw.h>
#include "hw_ta.h"  // my HW register definitions for target

unsigned char mybuf[10];
//...
iowr(MYPORT1, 0x8);  // write single register
for (int i = 0; i < 10; i++)
    mybuf[i] = iordbuf(MYPORT2, i);  // read register array
```

Page 78 of 138
In C++:

```cpp
#include <hardware>
struct UCharBuf {
  unsigned char buffer[10];
};
#include "hw_ta.h" // my HW register definitions for target
// contains:
// definitions of MyPort1T, MyPort2T, MyPort3T
// the value type for MyPort3T is UCharBuf

unsigned char mybuf[10];
using namespace std::hardware;
...
MyPort1T myPort1; // define HW register object
myPort1 = 0x08; // write single register
MyPort2T myPort2;
for (int i = 0; i < 10; i++)
  mybuf[i] = myPort2[i]; // read register array byte wise
MyPort3T myPort3;
UCharBuf mybufBlock;
mybufBlock = myPort3; // reads the whole register array at once
```

The programmer only sees the characteristics of the I/O register itself. The underlying platform, bus architecture, and compiler implementation do not matter during driver programming. The underlying system hardware may later be changed without modifications to the I/O driver source code being necessary.

### 4.1.4 Hardware Register Characteristics

The principle behind `iohw` is that all hardware register characteristics should be visible to the driver source code, while all platform specific characteristics are encapsulated by the header files and the underlying `iohw` implementation.

Hardware registers often behave differently from the traditional memory model. They may be “read-only”, “write-only” or “read-modify-write”, often read and write operations are only allowed once for each event, etc.

All such hardware register specific characteristics should be visible at the driver source code level and should not be hidden by the `iohw` implementation.

### 4.1.5 The Most Basic Hardware Access Operations

The most common operations on I/O-Hardware registers are “read” and “write”.

Bit-set, bit-clear and bit-invert of individual bits in an `iohw` register are also commonly used operations. Many processors have special machine instructions for doing these.

For the convenience of the programmer, and in order to promote good compiler optimisation of bit operations, the basic logical operations “or”, “and” and “xor” are defined by `iohw` in addition to “read” and “write”.

---

Page 79 of 138
All other arithmetic and logical operations used by the driver source code can be built
on top of these few basic operations.

4.1.6 The access-specification

The access specifications defined in iohw are used only as parameters in the functions
for defining hardware register access.

The access specification parameter represents or references a complete description of
how the hardware register should be addressed in the given hardware platform. It is
an abstract data type with a well-defined behaviour\(^{26}\).

The definition method and the implementation of access-specifications are processor
and platform specific.

In general, an access-specification will specify at least the following characteristics:

- Register size (mapping to a data type)
- Access limitations (read-only, write-only)
- Bus address for register

Other access characteristics typically specified via the access-specification:

- Processor bus (if more than one)
- Access method (if more than one)
- Hardware register endianness (if register width is larger than the device bus
  width)
- Interleave factor for hardware register buffers (if bus width for the device is
  smaller)
- User supplied access driver functions

The definition of a hardware register object may or may not require a memory
instantiation, depending on how a compiler vendor has chosen to implement access
specifications. In general, iohw implementors should provide optimised
implementations where the definition of an object of an access-specification type does
not produce any overhead. The concrete implementation techniques will differ and be
dependent on specific architecture, compiler and programming language.

See also Appendix A: for further details and implementation considerations.

4.2 Interface Definitions

This section defines both the C-style and C++-style interfaces.

The iohw C-style interface is a copy of the iohw C interface from Technical Report
ISO/IEC WDTR 18037 “Extensions for the programming language C to support
embedded processors,” included here as a convenience to the reader. If ever this copy
differs from the original in WDTR 18037, that original takes precedence.

\(^{26}\) This use of an abstract data type is similar to the philosophy behind the well-known FILE type in C. Some general properties
for FILE and streams are defined in the Standard, but the Standard deliberately avoids describing how the underlying file system
should be implemented.
4.2.1 The `<iohw.h>` interface

The header `<iohw.h>` declares several function-like macros which together create a data type-independent interface for basic I/O hardware addressing.

4.2.1.1 Function-like macros for single register access

Synopsis

```c
#include <iohw.h>

ior( access_spec )
iow( access_spec, value )
ioor( access_spec, value )
ioand( access_spec, value )
ioxor( access_spec, value )
```

Description

These names map an `iohw` register operation to an underlying (platform specific) implementation which provides access to the I/O register identified by `access_spec`, and perform the basic operations `READ`, `WRITE`, `OR`, `AND` or `XOR` as identified by the function name on this register.

The data type (the I/O register size) for `value` parameters and the value returned by `ior` is defined by the `access_spec` definition for the given register. The macro-like functions `iowr`, `ioor`, `ioand` and `ioxor` do not return a value.

Note (Lois): Should “macro-like functions” be “function-like macros” here?

4.2.1.2 Function-like macros for register buffer access

Synopsis

```c
#include <iohw.h>

iorbuf( access_spec, index )
iowbuf( access_spec, index, value )
ioorbuf( access_spec, index, value )
ioandbuf( access_spec, index, value )
ioxorbuf( access_spec, index, value )
```

Description

These names map an `iohw` register buffer operation to an underlying (platform specific) implementation which provides access to the I/O register buffer identified by `access_spec`, and perform the basic operations `READ`, `WRITE`, `OR`, `AND` or `XOR` as identified by the function name on this register.
The data type (the I/O register size) for value parameters and the value returned by iordbuf is defined by the access_spec definition for the given register. The functions iowrbuf, ioorbuf, ioandbuf and ioxorbuf do not return a value.

The index parameter is an offset in the register buffer (or register array) starting from the I/O location specified by access_spec, where element 0 is the first element located at the address defined by access_spec, and element \( n+1 \) is located at a higher address than element \( n \).

It should be noted that the index parameter is the offset in the I/O hardware buffer, not the processor address offset. Conversion from a logical index to a physical address requires that interleave calculations are performed by the underlying implementation. This is discussed further in A.2.2.

### 4.2.1.3 Function-like macros for access_spec initialisation

**Synopsis**

```
#include <iowh.h>

io_at_init( access_spec )
io_at_release( access_spec )
```

**Description**

The \texttt{io_at_init} function maps to an underlying (platform specific) implementation, which provides any access-specification initialisation before performing any other operation on the I/O register (or set of I/O registers) identified by \texttt{access_spec}. This macro should be placed in the driver source code so it is invoked at least once before any other operations on the related registers are performed. This function does not return a value.

**Editor’s Note:** The terms call, function and macro are not used in a consistent fashion throughout this and other sections. Also, the term I/O register is used several times in this section, while the term hardware register is used elsewhere.

The \texttt{io_at_release} function maps to an underlying (platform specific) implementation which releases any resources obtained by a previous call to \texttt{io_at_init} for the same access specification. This call should be placed in the driver source code so it is invoked once after all operations on the related registers have been completed. This function does not return a value.

**Example**

In an implementation for a hosted environment, the call to \texttt{io_at_init} is used to identify the point in an execution sequence where the underlying access method should obtain, or have obtained, a handle from the operating system. This handle is used in all following access operations on the I/O register. The call to \texttt{io_at_exit} identifies the point in an execution sequence where the handle can be returned to the operating system.
If a set of memory mapped I/O registers is specified to use based addressing (defined in Appendix F.), the underlying implementation would dynamically obtain the base address for the I/O range from the operating system when `io_at_init` is invoked (i.e. the base pointer is initialised). During all the following I/O access operations, the I/O register address is calculated as `(base_address + I/O register offset)`. The underlying implementation later releases the memory range when `io_at_exit` is invoked.

If no `access specification` specific initialisation is required by a given `<iohw.h>` implementation, the `io_at_init` and `io_at_release` definitions may be empty.

### 4.2.1.4 Functions for `access_spec` copying

**Synopsis**

```c
#include <iohw.h>

io_at_cpy( access_spec dest, access_spec src )
```

**Description**

This function maps to an underlying (platform specific) implementation, which copies the dynamic part of the source `access_spec` to the destination `access_spec`. The two parameters must have the same `access specification` type. This function does not return a value.

If `access-specification` copying is not supported by a given `<iohw.h>` header implementation, or a given `access-specification` does not contain any dynamic elements, the `io_at_cpy` function may be empty.

A typical use for `io_at_cpy` is when a set of driver functions for a given I/O device type are used with multiple hardware instances of the same device. It often provides a faster alternative than passing the `access_spec` as a function parameter.

**Example**

```c
#include <iohw.h>

#include "iohw_ta.h"  // MYDEV_CFG and MYDEV_DATA are defined relative to a dynamic MYDEV_BASE

// Portable driver function
uint8_t my_device_driver(void)
{
    iowr(MYDEV_CFG, 0x33);
    return iord(MYDEV_DATA);
}

// User’s driver application
uint8_t d1, d2;
```

**Editor’s Note:** The term chip is not correct. In an ASIC, FPGA or other SoC, the term device is used. A chip refers to a physical entity on which electronic circuits are described. This is ESPECIALLY true for embedded systems, which is the target audience of this TR.
// Read from our 2 I/O chips
io_art_cpy(MYDEV_BASE, CHIP1); // Select chip 1
d1 = my_chip_driver();
io_art_cpy(MYDEV_BASE, CHIP2); // Select chip 2
d2 = my_chip_driver();

### 4.2.2 The C++ Interface <hardware>

<table>
<thead>
<tr>
<th>Note (Detlef): Incomplete. This is essentially a description of my header file &lt;hardware&gt;.</th>
</tr>
</thead>
<tbody>
<tr>
<td>This is not completely up to date. The descriptions in Using Guidelines are newer, as well as the accompanying C++ files hardware.h and hardware.cpp.</td>
</tr>
</tbody>
</table>

The header <hardware> declares several types, which together provide a data-type-independent interface for basic I/O-Hardware addressing.

**Header <hardware> synopsis:**

```c
// proposed definition of <hardware>
// this is definition only
namespace std {
    namespace hardware {
        #include <stdint.h>

        struct hw_base;

        // required access types
        template <typename ValueType, 
                hw_base::device_bus devWidth, 
                hw_base::byte_order endian, 
                hw_base::processor_bus nativeWidth, 
                hw_base::address_type address>
            class direct_address;

        // [others still missing]
        template <typename ac_type>
            class register_access;
    } // namespace hardware
} // namespace std
```

### 4.2.2.1 Header <stdint.h>

The header <stdint.h> is specified by C99 (IS 9899-1999). Including it in <hardware> introduces the fixed size integer types into namespace std::hardware.

No names are introduced into global namespace.
4.2.2.2 struct hw_base

Synopsis

```cpp
struct hw_base;
namespace std {
    namespace hardware {
        struct hw_base {
            enum device_bus {device8, device16, device32, device64};
            enum byte_order {msb_low, msb_high};
            enum processor_bus {bus8, bus16, bus32, bus64};
            // only identifiers should be present that are supported
            // by the underlying implementation -- Diagnostic required
            typedef implementation defined address_type;
        };
    } // namespace hardware
define std
```

Description

struct hw_base

- provides the names for the supported hardware characteristics. Only those
  names that are supported by the hardware shall be present.

enum device_bus {device8, device16, device32, device64};
- defines the names for the width of the hardware register device bus as seen
  from the processor.

enum byte_order {msb_low, msb_high};
- defines the names for the endianness of the device register.

enum processor_bus {bus8, bus16, bus32, bus64};
- defines the names for the width of the processor bus.

address_type
- is an integral type specified by the application to hold a hardware address.

An implementation may define additional names and types in hw_base.

4.2.2.3 Common specifications for access-specification types

typename ValueType

- All access-specification template types have at least a `ValueType` parameter. The argument for this parameter shall be an Assignable and
  CopyConstructible type.

- The arguments for `ValueType` are not restricted to integral values. [Note: e.g.
  it makes perfect sense for `ValueType` to be double or long double when
  accessing an external floating-point co-processor. It might even be useful
  sometimes to have a user-defined `struct` as `ValueType`.

- The memory location of an object of the `ValueType` argument shall be
  readable and writeable freely by the implementation of this interface. [Note:
  This requirement essentially disallows other hardware registers or types.
Also, their value might be changed through the implementation by direct memory access instead of any (possibly overloaded) assignment operators.

- Most of the access-specification types have a common set of template parameters, which are specified as follows:

```
hw_base::device_bus devWidth
```
- `devWidth` defines the width of the device to be accessed as seen by the processor.
- `sizeof(ValueType)` must be a whole multiple (including 1) of `devWidth`.

```
hw_base::byte_order endian
```
- `endian` defines whether the device attached to the bus is to be accessed as little-endian or big-endian.

```
hw_base::processor_bus nativeWidth
```
- `nativeWidth` defines the width of the processor bus.
- All access-specification types may have additional template parameters specified by the implementation. The implementation may also define default arguments for some of the template parameters. [e.g. on segmented architectures there might be an additional segment parameter]

### 4.2.2.4 template<...> struct direct_address

**Synopsis**

```cpp
// required access types
template <typename ValueType,
    hw_base::address_type address,
    hw_base::device_bus devWidth,
    hw_base::byte_order endian,
    hw_base::processor_bus nativeWidth>
struct direct_address
{
    typedef ValueType value_type;

    template <hw_base::address_type other_address> struct rebind
    {
        typedef direct_address<ValueType,
            other_address,
            endian,
            nativeWidth,
            devWidth> other;
    };
};
```

**Note (Lois):** Looking at the two references to direct_address here, plus the one in 4.2.2, we seem to be giving the template parameters in three different orders. Also note that it is class direct_address in 4.2.2 and struct direct_address here. Detlef, could you look this over again please?
Description

direct_address

- defines the access-specification type for hardware registers for which the hardware address is known at compile time and the register addresses are directly mapped to memory addresses.

hw_base::address_type address

- The argument to address shall be the actual address of the hardware register to be accessed by this access specification type.

typedef ValueType value_type;

- value_type holds the ValueType template parameter.

struct rebind<...>::other

- rebind::other is a type with the same hardware characteristics but a different hardware register address.

[other access specification types follow]

4.2.2.5 class-template register_access

Synopsis

template <typename ac_type>
class register_access
{
    public:
        typedef typename ac_type::value_type value_type;

        operator value_type() const;
        void operator=(value_type val) const;
        void operator|=(value_type val) const;
        void operator&=(value_type val) const;
        void operator^=(value_type val) const;

        struct _ref
        {
            implementation defined constructor(s)
            operator value_type() const;
            void operator=(value_type val) const;
            void operator|=(value_type val) const;
            void operator&=(value_type val) const;
            void operator^=(value_type val) const;
        };

        _ref operator[](size_t index) const;
    }

Description

class register_access<...>

- provides direct access to hardware registers.

typename ac_type

- The argument to the template parameter ac_type must be an instantiation of an access specification template type (or a plain class) provided by the implementation.
ac_type::value_type value_type
• names the value_type of the access specification.

operator value_type() const
• provides read access to the hardware register.

void operator=(value_type val) const
• writes the value_type argument val to the hardware register.

void operator|=(value_type val) const
• bit-wise ors the hardware register with the value_type argument val.

void operator&=(value_type val) const
• bit-wise ands the hardware register with the value_type argument val.

void operator^=(value_type val) const
• bit-wise xors the hardware register with the value_type argument val.

struct _ref;
• provides the same overloaded operators as register_access to allow the same operations. [Note: The name _ref is here given for illustration purposes only. The actual implementation may use a different name. This name shall not be used directly by the user.]

_ref operator[](size_t index) const
• returns the equivalent to a reference to the location specified by index inside of the hardware register. The return value can be used like a register_access object, i.e. it can be written, read, and the bit-wise or, and and xor can be applied to it.

Editor's Note: Should the above operators really be const? It would seem to me that since they all semantically indicate that the object is altered, that the const should not be present (well except for the UDC to value_type).

Note (Detlef): I have omitted the function interface for now. If anybody thinks it is really important, please feel free to add it.

Note (Lois): I think it is important, but don't want to delay the document at this point. To be added later.

4.3 Guidelines for Using the iohw Interfaces

Note (Detlef): This will include some general examples and usage descriptions for using the interfaces (mainly C++, but with references to the C interface and examples shown in C and C++).

4.3.1 Usage Introduction
The design of the C++ iohw interface follows two lines of separation between:
• the definition of access specifications and device driver code
• what is known at compile-time and what is only known at run-time

Page 88 of 138
Unfortunately, these two lines of separation are neither orthogonal nor identical, for example, the base address for base/offset addressing is only known at run-time, but belongs to the access specification.

As C++ is a typed language, the differences for the interface are in type, and therefore the main separation line for the interface definition itself is between what is statically known at compile-time (this goes as template arguments into types) and what is only known at run-time (this goes as function arguments or operator operands into the interface of register_access).

4.3.2 access-specifications

access-specifications specify how a given device register can be accessed. As such, they are mainly implementation defined entities, as these access details vary widely over different platforms. But there are some aspects that access-specifications have in common:

- templates with at least ValueType as template parameter
- exposition of this ValueType argument as value_type typedef
- a “template typedef” rebind to provide a simple way to define access specifications that differ from an existing one only in a specific aspect (typically the hardware address)

Also, on platforms where they are available, the names of some access-specification templates are pre-defined:

- direct_address for memory-mapped addresses that are known at compile-time.

  This has at least three template arguments: ValueType, mode (read, write, etc.) and address. So on some platforms the user should be able to define a specific hardware port like this:

  typedef direct_address:uint16_t, hw_base::read, 0x1234> InPort1;

- dynamic_address for memory-mapped addresses that are only known at runtime

This assumes that the hardware register is 16-bits, and all other characteristics are pre-defined by the platform’s implementation. But on most implementations, the user has to specify additional template parameters. But as already said, these template parameters are platform dependent and can vary widely for more exotic platforms. Even the address parameter might vary; for example, on a segmented addressing architecture there might be two parameters for a segment and an offset address instead of a single address parameter.

If there already exists a quite elaborate type definition ComplexPortA for a specific device register with lots of template arguments and now another one is required with the same characteristics that differs only in its hardware address, this can be done with the rebind template:

  typedef ComplexPortA::rebind<0x9876>::other ComplexPortB;
4.3.2.1 access-specifications with dynamic information

Some access-specifications may require additional information that is not available at compile-time. For those access-specifications, the access specification template defines an additional parameter for the type of the dynamic data. The properties of this type are defined by the implementation, but the type itself is provided by the user to allow user-control of the initialisation.

For example, an implementation might provide a dynamic_address for which the dynamic data type must provide a public data member address of type unsigned long. Then the user can provide a corresponding class:

```c
struct DynAddressPortDA
{
    DynAddressPortDA() : address(globalBase+0x120) {}
    unsigned long address;
};
typedef dynamic_address< uint32_t, hw_base::random,
            DynAddressPortDA> PortDA_t;
```

Here, the initialisation of the dynamic data is provided by some global variable.

As another example, on a different platform an implementation might require for the dynamic data two public data members segment and offset, both of type unsigned short. A user class may look like this:

```c
struct DynAddressPortDB
{
    DynAddressPortDB(unsigned short off) :
        segment(0xF0), offset(off)
    {}
    unsigned short segment;
    unsigned short offset;
};
typedef dynamic_address< uint32_t, hw_base::random,
            DynAddressPortDB> PortDB_t;
```

Here, the constructor requires an argument. Therefore some initialisation code must provide that argument. But the mechanics of the initialisation are always left to the user to choose the best fitting method.
4.3.3 Hardware Access

All hardware access is provided through the class-template register_access. For access-specifications that require no dynamic information the respective register_access objects contain no data and therefore are optimised completely out of existence by most compilers. So, a typical usage might be:

```cpp
// defined access-specifications with ValueType = uint8_t:
// InPort, OutPort and ControlPort
register_access<InPort> ip;
register_access<OutPort> op;
register_access<ControlPort> ctl_p;

uint8_t tmp = ip; // read from InPort, uses
    // register_access::operator value_type();
op = 0x12; // write to OutPort, uses
    // register_access::operator=(value_type);
ctl_p |= 0x34; // set bits 5, 4 and 2 in ControlPort
```

As the register_access object is empty, there is no real need to define these objects, but it is also possible to use temporary objects created on the fly. The example above would then become:

```cpp
// defined access-specifications with ValueType = uint8_t:
// InPort, OutPort and ControlPort
typedef register_access<InPort> InP;
typedef register_access<OutPort> OutP;
typedef register_access<ControlPort> CtlP;

uint8_t tmp = InP(); // read from InPort, uses
    // register_access::operator value_type();
OutP() = 0x12; // write to OutPort, uses
    // register_access::operator=(value_type);
CtlP() |= 0x34; // set bits 5, 4 and 2 in ControlPort
```

But this is a rather unnatural syntax and is generally not necessary as compilers are smart enough to optimise away the objects from the first example.

4.3.3.1 Indexed Access

register_access allows not only for access to single registers, but also for register blocks. The ValueType parameter of the access-specification denotes in this case the type of a single register and the address is the base address (index 0). The registers in the block can then be addressed through the index (subscript) operator:

```cpp
// assume register block PortBuffer with random access
register_access<PortBuffer> portBuf;
uint8_t buf[sz];

portBuf[0] &= 0x03;
portBuf[1] = sz - 2;

for (int i=2; i != sz; ++i)
    buf[i] = portBuf[i];
```
If a full register block is always to be accessed, a respective `ValueType` can be defined:

```c
struct Buffer32 { uint8_t data[32]; }; 
typedef direct_address<Buffer32, 
    hw_base::random,
    0x35800,
    ...> XYBlock; 
register_access<XYBlock> blockBuf; 
Buffer32 tmpBlock; 

tmpBlock = blockBuf;  // read whole block at once
```

The binary layout of the `ValueType` must match the register block, which is normally only guaranteed for PODs. But if the register block has a complex layout (e.g. mix of different data types), the `ValueType` may be a correspondingly complex `struct`.

4.3.3.2 Initialisation of register_access

For static access-specifications that are fully specified at compile-time `register_access` provides only a default constructor (in these cases there is nothing to construct). But if the access specification contains dynamic data, this must be initialised at run-time. For those cases, `register_access` provides only a constructor that takes the dynamic data type of the access-specification as parameter. How this dynamic type is initialised is under control of the user, as explained above. So, regarding the examples from above, the initialisation can either be:

```c
register_access<PortDA_t> portDA=DynAddressPortDA();
```

or

```c
register_access<PortDB_t> portDB=DynAddressPortDB(portDBOffset);
```
Appendix A: Implementing the *iohw* Interfaces

(General Implementation Considerations)

| Editor’s Note: | This really belongs as an Appendix. This was discussed before and the decision was that it did not represent a normative part of the TR. I am not aware that this determination was reversed or reconsidered. Furthermore, the heading levels becomes really deep if it is not considered to be a separate Section or Appendix. |

A.1 Purpose

*iohw* defines a standardised function syntax for basic hardware addressing. The interface can either be provided by a library vendor or by the compiler vendor. If it is provided by the compiler vendor, it can contain special “compiler magic” that may be necessary to access special hardware with special addressing needs (or it might just provide better performance).

While a standardised function syntax for basic hardware addressing provides a simple, easy-to-use method for a programmer to write portable and hardware-platform-independent driver code, the *iohw* header itself may require careful consideration to achieve an efficient implementation.

This section gives some guidelines for implementers on how to implement *iohw* in a relatively straightforward manner given a specific processor and bus architecture.

A.1.1 Recommended Steps

Briefly, the recommended steps for implementing the *iohw* headers are:

- Get an overview of all the possible and relevant ways the hardware register is typically connected with the given bus hardware architectures, and get an overview of the basic software methods typically used to address such hardware registers.

- Define a number of functions, macros and *access-specifications* which support the relevant hardware access methods for the intended compiler market.

- Provide a way to select the right access function at compile-time and generate the right machine code based on the *access-specification* type or the *access-specification* value.

A.1.2 Compiler Considerations

In practice, an implementation will often require that very different machine code is generated for different hardware access cases. Furthermore, with some processor architectures, hardware register access will require the generation of special machine
instructions not typically used when generating code for the traditional C or C++
memory model.

Selection between different code generation alternatives must be determined solely
from the access specification declaration for each hardware register. Whenever
possible, this access method selection should be implemented such that it may be
determined entirely at compile-time, in order to avoid any run-time or machine code
overhead.

For a compiler vendor, selection between code generation alternatives can always be
implemented by supporting different intrinsic access-specification types and
keywords designed specially for the given processor architecture, in addition to the
Standard types and keywords defined by the language.

However, with a conforming C++ compiler, an efficient, all-round implementation of
both the C and C++ interface headers can usually be made using template
functionality [Editor’s Note: How can the C interface be made using template
functionality? I think this needs a bit of rewording]. A template-based solution
allows the number of compiler specific intrinsic hardware access types or intrinsic
hardware access functions to be minimized or even removed completely, depending
on the processor architecture.

For compilers not supporting templates (such as C compilers) other implementation
methods must be used. In any case, at least the most basic iohw functionality can be
implemented efficiently using a mixture of macros, inline functions and intrinsic
types or functions.

For many architectures, fully featured, zero-overhead implementations of iohw can be
done using templates. An approach to doing this is discussed in 4.2.2. Nevertheless,
fully featured iohw implementations for several architectures will usually require
direct compiler support.

### A.2 Overview of Hardware Device Connection Options

The various ways of connecting an external device’s register to processor hardware
are determined primarily by combinations of the following three hardware
characteristics:

- The bit width of the logical device register
- The bit width of the data-bus of the device
- The bit width of the processor-bus

#### A.2.1 Multi-Addressing and Device Register Endian

If the width of the logical device register is greater than the width of the device data
bus, a hardware access operation will require multiple consecutive addressing
operations.
The device register endianness information describes whether the most significant byte (MSB) or the least significant byte (LSB) byte of the logical I/O register is located at the lowest processor bus address.

**Editor’s Note:** What about devices whose word size does not factor into bytes, for example, configurable devices from the “Silicon Intellectual Property” (SIP) sector?

(Note that the device register endianness is not coupled to the endianness of the underlying processor hardware architecture).

**Table A-1: Logical I/O register / I/O device addressing overview**

<table>
<thead>
<tr>
<th>Logical register width</th>
<th>device bus width</th>
<th>8-bit device bus</th>
<th>16-bit device bus</th>
<th>32-bit device bus</th>
<th>64-bit device bus</th>
</tr>
</thead>

<td>r16{0-3}</td>
<td>r16{3-0}</td>
<td>r32{0-1}</td>
</tr>
</tbody>
</table>

(For byte-aligned address ranges)

**A.2.2 Address Interleave**

If the size of the device data bus is less than the size of the processor data bus, buffer register addressing will require the use of *address interleave*.

For example:

If the processor architecture has a byte-aligned addressing range with a 32-bit processor data bus, and an 8-bit device is connected to the 32-bit data bus, then three adjacent registers in the device will have the processor addresses:

<addr + 0>, <addr + 4>, <addr + 8>

---

27 Note, that this table describes some common bus and register widths for I/O devices. A given hardware platform may use other register and bus widths.
This can also be written as

$$<\text{addr} + \text{interleave}^0>, <\text{addr} + \text{interleave}^1>, <\text{addr} + \text{interleave}^2>$$

where $\text{interleave} = 4$.

Table A-2: Interleave overview: (bus to bus interleave relationship)

<table>
<thead>
<tr>
<th>Device bus width</th>
<th>Processor bus width</th>
</tr>
</thead>

<td></td>
<td>MSB</td>
</tr>
<tr>
<td></td>
<td>n/a</td>
<td>1</td>
</tr>
</tbody>
</table>

(For byte-aligned address ranges)

### A.2.4 Generic Buffer Index

The interleave distance between two logically adjacent registers in a device register array can be calculated from\(^{28}\):

- The size of the logical register in bytes
- The processor data bus width in bytes
- The device data bus width in bytes

---

\(^{28}\) For systems with byte-aligned addressing.
Conversion from register index to address offset can be calculated using the following general formula:

\[
\text{Address\_offset} = \text{index} \times \\
\quad \text{sizeof( logical\_IO\_register )} \times \\\text{sizeof( processor\_data\_bus )} / \\\text{sizeof( device\_data\_bus )}
\]

Assumptions:

- bytes are 8-bits wide
- address range is byte-aligned
- data bus widths are a whole number of bytes
- width of the logical\_IO\_register is greater than or equal to the width of the device\_data\_bus
- the width of the device\_data\_bus is less than or equal to the processor\_data\_bus

A.3 access-specifications for Different Device Addressing Methods

An implementer should consider the following typical addressing methods:

- **Address is defined at compile-time:**
  The address is a constant. This is the simplest case and also the most common case with smaller architectures.

- **Base address initialised at run-time:**
  Variable base-address + constant-offset i.e. the access-specification must contain an address pair (address of base register + offset of address).

  The user-defined base-address is normally initialised at run-time (by some platform-dependent part of the program). This also enables a set of driver functions to be used with multiple instances of the same device type.

- **Indexed bus addressing:**
  Also called orthogonal or pseudo-bus addressing. This is a common way to connect a large number of device registers to a bus, while still occupying only a few addresses in the processor address space.

  This is how it works: first the index-address (or pseudo-address) of the device register is written to an address bus register located at a given processor address. Then the data read/write operation on the pseudo-bus is done via the following processor address, i.e. the access-specification must contain an address pair (the processor-address of the indexed bus, and the pseudo-bus address (or index) of the device register itself).

<table>
<thead>
<tr>
<th>Editor’s Note:</th>
<th>Presumably this has to be performed as an atomic operation, protected thread scheduling or interrupts handlers. Should we note this explicitly?</th>
</tr>
</thead>
</table>

Page 98 of 138
This access method also makes it particularly easy for a user to connect common devices that have a multiplexed address/data bus, to a processor platform with non-multiplexed busses, using a minimum amount of glue logic. The driver source code for such a device is then automatically made portable to both types of bus architecture.

- **Access via user-defined access driver functions:**

  These are typically used with larger platforms and with small single-chip processors (e.g. to emulate an external bus). In this case, the access specification must contain pointers or references to access functions.

The access driver solution makes it possible to connect a given device driver source library to any kind of platform hardware and platform software using the appropriate platform-specific interface functions.

In general, an implementation should always support the simplest addressing case, whether it is the constant-address or base-address method that is used will depend on the processor architecture. Apart from this, an implementer is free to add any additional cases required to satisfy a given domain.

Because of the different number of parameters required and the parameter ranges used in an access-specification, the C++ interface requires the definition of different access-specification templates for each of the different addressing methods. For the C interface, it is often convenient to do the same and therefore implementing the C interface on top of the C++ interface.

---

**Note (Lois):** The preceding paragraph needs some more work. It leaves the impression that a C-style programmer also wants to define several type templates, a syntactic impossibility. I suggest something more general, like:

"The C++-style interface using combinations of type templates provides greater type safety than the function-style macros. However, programmers using the common subset of C and C++ can still take advantage of this benefit by implementing `<iohw.h>` on top of the C++ code. See section A.8 for more detailed discussion."

---

### A.4 Atomic Operation

It is a requirement of the `iohw` implementation, that in each `iohw` function, a given (partial\(^29\)) device register is addressed exactly once during a read or a write operation and exactly twice during a read-modify-write operation.

It is recommended that each `iohw` function in an `iohw` implementation, be implemented such that the device access operation becomes atomic whenever possible. However, atomic operation is not guaranteed to be portable across platforms for the logical read-modify-write operations (i.e. the or, and, and xor operations) or for multi-addressing cases. The reason for this is simply that many processor

---

\(^{29}\) A 32-bit logical register in a device with an 8-bit data bus contains 4 partial I/O registers.
architectures do not have the instruction set features required for assuring atomic operation.

A.5  Read-Modify-Write Operations and Multi-Addressing

<table>
<thead>
<tr>
<th>Note (Detlef):</th>
<th>Jan, how do you specify multi-address in your interface?</th>
</tr>
</thead>
</table>

On processor architectures where the modifying operations (or, and, xor) can not be realised as single instruction operations, an implementation shall provide an access-specification that guarantees a complete read – modify – complete write realisation for the modifying operations.

The rationale for this restriction is to allow iohw uses to use the lowest common denominator of multi-addressing hardware implementations in order to support the widest possible range of iohw register implementations.

For instance, more advanced multi-addressing device register implementations often take a snap-shot of the whole logical device register when the first partial register is being read, so that data will be stable and consistent during the whole read operation. Similarly, write registers are often “double-buffered”, so that a consistent data set is presented to the internal logic at the time when the access operation is completed by the last partial write.

Such hardware implementations often require that each access operation be completed before the next access operation is initiated.

A.6  Initialisation

With respect to the standardisation process, it is important to make a clear distinction between hardware (device) related initialisation, and platform related initialisation. Typically, three types of initialisation are related to device register operation:

- hardware (device) initialisation
- access-specification initialisation
- device selector initialisation

Here only access specification initialisation and device selector initialisation are relevant for the specification of iohw:

**Hardware Initialisation:** This is a natural part of a hardware driver, and should always be considered part of the device driver application itself. This initialisation is done using the standard functions for basic iohw addressing. Hardware initialisation is therefore not a topic for the standardisation process.

**Access-specification Initialisation:** This concerns the initialisation and definition of the access_spec objects themselves.

For many access-specifications, there is no run-time initialisation necessary. However, for some access methods, some run-time initialisation is required.

---

30 If for instance the access method is implemented as \( \text{base_address} + \text{constant_offset} \) then "device selector initialisation" refers to assignment of the base_address value.
using the \texttt{iohw} C-style interface, the function:

\begin{verbatim}
io_at_init(access_spec)
\end{verbatim}

can be used as a portable way to specify in the source code where and when such initialisation should take place.

| Note (Detlef): | Sorry, but I can’t see how you can provide a base address using \texttt{io_at_init}. |

The \texttt{iohw} C++ interface provides the constructor

\begin{verbatim}
template <typename initType>
register_access::register_access(initType);
\end{verbatim}

with an implementation defined \texttt{initType} for the same purpose.

**device selector initialisation:** This is used when, for instance, the same device driver code needs to service multiple devices of the same type.

A common possible solution is to define multiple \texttt{access specification} objects, one for each of the devices, and then have the \texttt{access-specification} passed to the driver functions from the calling function.

The \texttt{iohw} C-style interface provides another solution - the use \texttt{access-specification} copying, and \texttt{access-specifications} with dynamic access information:

\begin{verbatim}
io_at_cpy(access_spec dest, access_spec src)
\end{verbatim}

| Note (Detlef): | I’d like to see a real example of how this works. |
| Editor’s Note: | So would I. |

In C++, this is most easily accomplished by providing a template function with the \texttt{access specification} as template argument. For \texttt{access specifications} with no run-time information this requires no data transfer (i.e. no function parameters). For \texttt{access-specifications} with dynamic information, this dynamic information must be passed as function parameters. \texttt{rebind} in the \texttt{access-specification} provides a portable way to get an \texttt{access specification} that differs from a formerly defined \texttt{access-specification} in only one parameter.

With most freestanding environments and embedded systems, the platform hardware is well defined; so all \texttt{access-specifications} for device registers used by the program can be completely defined at compile-time. For such platforms, standardised \texttt{access specification} initialisation is not an issue.

With larger processor systems, device hardware is often allocated dynamically at run-time. Here the \texttt{access-specification} information can only be partly defined at compile-time. Some platform dependent part of the software must be initialised at run-time.

When designing the \texttt{access_spec} objects, the or compiler or library implementer must therefore make a clear distinction between static information and dynamic
information; i.e. what can be defined and initialised at compile-time, and what must be initialised at run-time.

Depending on the implementation method, and depending on whether the access_spec objects need to contain dynamic information, the access_spec objects may or may not require instantiation in data memory. Better execution performance can usually be achieved if more of the information is static.

### A.7 Implementation Guidelines for the C++ Interface

**Note (Detlef):** This will contain guidelines to get zero-overhead.

There are two main design alternatives in implementing register_access for the different access-specifications:

- Using the access-specifications as full-fledged traits classes that contain the information for register_access to behave accordingly (this is the approach chosen in the sample implementation).
- Using the access-specifications as mere labels and specializing register_access for each of these access specifications (this is a useful approach if there are very few commonalities between the different access-specifications).

In any case, carefully implemented specializations of helper classes used in register_access can provide resulting code that only contains the necessary hardware access statements and produces absolutely no overhead.

The ultimate hardware access statements will nearly always be realized either as inline assembler or as compiler intrinsics. But this is hidden in the implementation; the user does not see them.

**Note (Detlef):** The rest of this section will be a mere walk-through of the attached code hardware.cpp.

### A.8 Implementing the C interface in Terms of the C++ Interface

**Note (Detlef):** This will contain a full implementation example plus the old Appendix B.

**Editor’s Note:** I have moved the old Appendix B back to Appendix B. See previous note regarding normative text in the TR. This does need work.
Appendix B: Generic access specification for iohw Addressing

B.1 Generic access-specification Descriptor
This appendix proposes a consistent and complete specification syntax for defining device registers and the access method parameters for the iohw C-style interface (i.e. though the syntax is C++ style for access specifications, it is intended to be callable from code written in the common subset interfacing with the device register address level).

Note (Lois): Jan and Detlef, is this change OK?

Prior art has used a number of (compiler intrinsic) memory type qualifiers or special keywords, which have varied from compiler to compiler and from platform to platform. The syntax described below represents an alternative approach and a subset solution, intended to replace prior art.

For optimal performance, the compiler should pick the right access method implementation at compile-time based on the access-specification type. This can be achieved in C++ by using typedefs and template specialisations.

B.2 Syntax Specification
access_spec specification:

    typedef ACCESS_METHOD_CLASS_NAME < parameter list > SYMBOLIC_PORT_NAME;

parameter list:

    access method independent parameter list, access method specific parameter list

access method independent parameter list:

    type for device register value (size of device register), access limitation type, device bus type (size and endianness of device bus)

type for device register value (size of device register):

    uint8_t
    uint16_t
    uint32_t
    uint64_t
    bool

    (+ optionally any basic type native to the implementation)
access limitation type: // for compile-time diagnostic

```
rmw_e    // read_modify_write
rw_e     // read_write
wo_e     // write_only
ro_e     // read_only
```

device bus type:

```
device8   // register width = device bus width = 8 bit
```

Note (Jan): The definitions device8l and device8h concern the use of bus widths less than 8-bits and are to be removed as the entire chapter only refers to register bus widths of 8-, 16-, 32- and 64-bits.

Editor’s Note: I’d like to know more about support for devices other than those with 8-, 16-, 32- or 64-bit widths. This continuously eludes me.

device8l  // register width > device bus width, MSB on low address
device8h  // register width > device bus width, MSB on high address
device16l // register width = device bus width = 16 bit
device6l  // register width > device bus width, MSB on low address
device16h // register width > device bus width, MSB on high address
device32  // register width = device bus width = 32 bit
device32l // register width > device bus width, MSB on low address
device32h // register width > device bus width, MSB on high address
device64  // register width = device bus width = 64 bit
(+ optionally any bus width native to the implementation)

access method specific parameter list:

```
// Depends on the given access method. Examples are given later.
// Three typical parameters are:
// primary address constant ,
processor bus width type,
address mask constant
```

processor bus width type:

```
bw8      // 8 bit bus
bw16     // 16 bit bus
bw32     // 32 bit bus
bw64     // 64 bit bus
(i.e. any bus widths native to the implementation)
```

### B.2.1 Bus Connection Parameters

The possible device register to bus connections can be completely specified using only two parameters:

- A bus parameter, which specifies the access relationships between the device data bus and the processor data bus
- A multi-addressing and endian parameter, which specifies the access relationships between the logical device register and the device data bus
For example, a possible definition of general device register connection types might be:

```c
enum bus_t { bw8 = 1, bw16 = 2, bw32 = 4, bw64 = 8 };
enum device_t { device8, device16, device16l, device16h,
               device32, device32l, device32h, device64 };
```

For another example, an implementation for a given processor architecture may only support a subset of the device register connection types. Possible device register connections with the processor H8/300H (supporting only an 8-bit and a 16-bit processor data bus):

```c
enum bus_t { bw8 = 1, bw16 = 2 };
enum device_t { device8, device16, device16l, device16h };
```

### B.2.2 Detection of Read / Write Violations in Device Registers

The `access-specifications` can specify a `limitation` parameter, which makes it possible to detect illegal use of a device register at compile-time.

The minimal parameter set for a read / write limitation specification would be:

- Defined as Read-Modify-Write register (behaves like a RAM cell)
- Defined as Read and Write register (read value may be different from write value)
- Defined as Write-Only register
- Defined as Read-Only register

**Table B-1: Allowed operations on different device register types:**

<table>
<thead>
<tr>
<th>Access Type</th>
<th>iowr</th>
<th>iord</th>
<th>ioor</th>
<th>ioand</th>
<th>ixor</th>
</tr>
</thead>
<tbody>
<tr>
<td>Read-Modify-Write</td>
<td>Yes</td>
<td>Yes</td>
<td>Yes</td>
<td>Yes</td>
<td>Yes</td>
</tr>
<tr>
<td>Read-and-Write</td>
<td>Yes</td>
<td>Yes</td>
<td>No</td>
<td>No</td>
<td>No</td>
</tr>
<tr>
<td>Write-Only</td>
<td>Yes</td>
<td>No</td>
<td>No</td>
<td>No</td>
<td>No</td>
</tr>
<tr>
<td>Read-Only</td>
<td>No</td>
<td>Yes</td>
<td>No</td>
<td>No</td>
<td>No</td>
</tr>
</tbody>
</table>

The “not-allowed” cases should generate some kind of error message at compile-time. With a template implementation of `<iowr.h>`, the compiler will typically diagnose that no matching `function-template` can be found for the “not-allowed” cases.
For example:

```cpp
// --- part of the <iowh.h> header

enum rw_t // Access mode type {
  rmw_e, // Read-Modify-Write access
  rw_e, // Read-and-Write access
  wo_e, // Write-Only access
  ro_e // Read-Only access
};

// Include 'exact-width' integer types (defined in the header
// 'stdint.h' in C)
#include <stdint.h> // Or possibly <cstdint>31

// Define access_spec template for direct addressing
template <class T, rw_t access, device_t devicetype,
  address_t address, bus_t buswidth>
class IO_MM {
  ...
};

// --- part of the "iowh_ta.h" header

// User declaration of device registers in platform
typedef IO_MM <uint8_t, wo_e, device8, 10200, bw8> WR_PORT;
typedef IO_MM <uint8_t, ro_e, device8, 20400, bw8> RD_PORT;
typedef IO_MM <uint8_t, rmw_e, device8, 20800, bw8> RDWR_PORT;

// --- portable user code
uint8_t myval;
myval = iord(RD_PORT); // ok
myval += iord(RDWR_PORT); // ok
iowr(WR_PORT, myval); // ok
iowr(RDWR_PORT, 0x45); // ok

myval = iord(WR_PORT); // Illegal, generate compile-time error
iowr(RD_PORT, 0x55); // Illegal, generate compile-time error
```

---

31 ISO C++ was ratified in 1997. At that time, the header file `<cstdint.h>` was not present in ISO C, and was added to ISO C in 1999. The naming convention used for C headers by ISO C++ would result in this being known as `<cstdint>`. 

---

Page 106 of 138
B.2.3 access-specifications for Different Processor Busses

An implementation shall define at least one access method for each processor addressing range. If the processor architecture has multiple different addressing ranges (i.e. it requires different sets of machine instructions for the different busses), each addressing range should have its own set of access-specifications.

For example, on the 80x86 family, an implementation must define at least two sets of access methods; one for the memory-mapped range, and another for the I/O mapped range:

```c
typedef uint32_t address_t;  // Memory-mapped address range
typedef uint8_t io_addr_t;   // I/O-mapped address range

template <class T, rw_t access, device_t devicetype, address_t address, bus_t buswidth>
  class IO_MM { };
template <class T, rw_t access, device_t devicetype, 
          io_addr_t address, bus_t buswidth>
  class IO_IOM { };
```

B.2.4 access-specifications for Different Access Methods

If several different access methods are supported for a given address range, then an access-specification must exist for each access method.

For example:

```c
// Define types used in access_spec declarations
typedef uint32_t address_t;  // Memory mapped address range
typedef uint8_t sub_address_t; // Sub address on indexed bus
typedef uint16_t io_addr_t;   // User device driver address
typedef uint8_t bit_pos_t;    // Bit position in register

template <class T, rw_t access, device_t devicetype, 
          address_t address, bus_t buswidth>
  class IO_MM { };

template <class T, rw_t access, device_t devicetype, 
          address_t address, bus_t buswidth>
  class IO_MM_BASE { };

template <class T, rw_t access, device_t devicetype, 
          address_t address, sub_address_t idx, bus_t buswidth>
  class IO_MM_IDX { };

template<class T, rw_t access, io_addr_t address, 
          T iord( io_addr_t address),
          void iowr( io_addr_t address, T val)>
  class IO_MM_DRV { };

template<class T, rw_t access, device_t devicetype, 
          address_t address, bit_pos_t bitpos, bus_t buswidth>
  class IO_MM_BIT { };
```
B.2.5 Optimisation Possibilities for Typical Implementations

B.2.5.1 Pre-Calculation of Constant Expressions

A high performance compiler would resolve all constant expressions at compile-time. Using inline functions, both interleave factors and constant buffer indices would be folded into the address value(s) used in the machine code.

Therefore, the following two I/O write statements would result in exactly the same machine code:

```c
iowr(PORT1, 0x33);
iowrbuf(PORT1, 0, 0x33);
```

An implementation can take advantage of this, because the number of hardware register access functions that have to be implemented can be reduced with no efficiency penalty using simple delegation, using inline-functions or macros such as:

```c
#define iowr(access_spec, val)    iowrbuf(access_spec, 0, (val))
```

or function-templates such as:

```c
template <class access_spec>
inline void iowr (typename access_spec::value_type val)
{
    iowrbuf<access_spec>(0, val);
}
```

B.2.5.2 Multi-Addressing and Endianness

Typical candidates for platform dependent optimisations are hardware iohw functions for the multi-addressing cases (logical device register width > device bus width) where the width of the device data bus matches the width of the processor data bus; for example, the combinations of:

- (device16h or device16l) and bw16
- (device32h or device32l) and bw32

In these cases, multi-byte access can often use data types that are directly supported by the processor for either the LSB or MSB endianness functions. The other endianness functions can often be implemented efficiently using one load or store operation, plus one or more register swap operations.

These references may serve as a starting point for finding more information about programming for performance.

Alexander, Rene, and Graham Bensley
C++ Footprint and Performance Optimization
Sams Publishing, 2000

More general than the Bulka-Mayhew book, and omits any mention of the containers and algorithms in the C++ Standard Library.

Bentley, Jon Louis
Writing Efficient Programs
Prentice-Hall, Inc., 1982

Unfortunately out of print, but a classic catalogue of techniques that can be used to optimise the space and time consumed by an application (often by trading one resource to minimise use of the other). Because this book predates the public release of C++, code examples are given in Pascal.

"The rules that we will study increase efficiency by making changes to a program that often decrease program clarity, modularity, and robustness. When this coding style is applied indiscriminately throughout a large system (as it often has been), it usually increases efficiency slightly but leads to late software that is full of bugs and impossible to maintain. For these reasons, techniques at this level have earned the name of "hacks"... But writing efficient code need not remain the domain of hackers. The purpose of this book is to present work at this level as a set of engineering techniques."

Bulka, Dov, and David Mayhew
Efficient C++: Performance Programming Techniques
Addison-Wesley, 2000

Contains many specific low-level techniques for improving time performance, with measurements to illustrate their effectiveness.

"If used properly, C++ can yield software systems exhibiting not just acceptable performance, but superior software performance."

Cusumano, Michael A., and David B. Yoffie
What Netscape Learned from Cross-Platform Software Development

Faster run-time performance brings commercial advantage, sometimes enough to outweigh other considerations such as portability and maintainability (an argument also advanced in the Bulka-Mayhew book).
Embedded C++ Technical Committee

**Embedded C++ Language Specification, Rationale, & Programming Guidelines**

http://www.caravan.net/ec2plus

EC++ is a subset of Standard C++ that excludes some significant features of the C++ programming language, including:

- exception handling (EH)
- run-time type identification (RTTI)
- templates
- multiple-inheritance (MI)
- namespaces

Glass, Robert L

**Software Runaways: Lessons Learned from Massive Software Project Failures**

Written from a management perspective rather than a technical one, this book makes the point that a major reason why some software projects have been classified as massive failures is for failing to meet their requirements for performance.

"Of all the technology problems noted earlier, the most dominant one in our own findings in this book is that performance is a frequent cause of failure. A fairly large number of our runaway projects were real-time in nature, and it was not uncommon to find that the project could not achieve the response times and/or functional performance times demanded by the original requirements."

Gorlen, Keith, et al.

**Data Abstraction and Object Oriented Programming in C++**

NIH 1990

Based on the Smalltalk model of object orientation, the “NIH Class Library” also known as the “OOPS Library” was one of the earliest Object Oriented libraries for C++. As there were no "standard" classes in the early days of C++, and because the NIHCL was freely usable having been funded by the US Government, it had a lot of influence on design styles in C++ in subsequent years.

Lippman, Stan  
Inside the C++ Object Model  
Explains typical implementations and overheads of various C++ language features, such as multiple inheritance and virtual functions. A good in-depth look at the internals of typical implementations.

Editor’s Note: The following bibliography entry has gone missing – was this intentional?

Lippman, Stanley B. and Lajoie, Josée  
C++ Primer, 3rd Edition  
Addison-Wesley, 1998  
This thorough introduction to C++ includes discussions of how various language constructs produce different executable code, plus measurements of run-time performance. For example, using reserve() to pre-allocate space for a vector resulted in slower execution times when the vector held strings or doubles, but faster times if the value type was a large, complex class.

Meyers, Scott  
Effective STL: 50 Specific Ways to Improve Your Use of the Standard Template Library  

In keeping with the philosophy of the Standard Library, this book carefully documents the performance implications of different choices in design and coding, such as whether to use map::operator[] or map::insert.
"The fact that function pointer parameters inhibit inlining explains an observation that long-time C programmers often find hard to believe: C++'s `sort` virtually always embarrasses C's `qsort` when it comes to speed. Sure, C++ has function- and class-templates to instantiate and funny-looking `operator()` functions to invoke while C makes a simple function call, but all that C++ "overhead" is absorbed during compilation... It's easy to verify that when comparing function objects and real functions as algorithm parameters, there's an abstraction bonus."

Mitchell, Mark
Type-Based Alias Analysis
Dr. Dobbs' Journal, October 2000.

Some techniques for writing source code that is easier for a compiler to optimise.

"Although C++ is often criticized as being too slow for high-performance applications, ... C++ can actually enable compilers to create code that is even faster than the C equivalent."

- Standard C++ as a High-Level Language? [Nov ‘99]  
- Replacing Character Arrays with Strings, Part 1 [Jan ‘00]  
- Replacing Character Arrays with Strings, Part 2 [Feb ‘00]

These articles are part of a series on migrating a C program to use the greater abstraction and encapsulation available in C++. The run-time and executable size are measured as more C++ features are added, such as Standard strings, **iostreams**, and containers.

"A seemingly small change in a string algorithm [such as reserving space for string data, or erasing the data as an additional preliminary step] might produce a surprisingly large change in program execution time."

The conclusion is that you should "program at the highest level of abstraction that you can afford".

Schilling, Jonathan  
**Optimizing Away C++ Exception Handling**  

This article discusses ways to measure the overhead, if any, of the exception handling mechanisms. A common implementation of EH incurs no run-time penalty unless an exception is actually thrown, but at a cost of greater static data space and some interference with compiler optimisations. By identifying sections of code in which exceptions cannot possibly be thrown, these costs can be reduced.

*This optimization produces modest but useful gains on some existing C++ code, but produces very significant size and speed gains on code that uses empty exception specifications, avoiding otherwise serious performance losses.*

Stroustrup, Bjarne  
**The C++ Programming Language, 3rd Edition**  
Addison-Wesley, 1998

This definitive work from the language’s author has been extensively revised to present Standard C++.
Stroustrup, Bjarne
The Design and Evolution of C++
Addison-Wesley, 1994

The creator of C++ discusses the design objectives that shaped the
development of the language, especially the need for efficiency.

"The immediate cause for the inclusion of inline functions ... was a project
that couldn’t afford function call overhead for some classes involved in real-
time processing. For classes to be useful in that application, crossing the
protection barrier had to be free. [...]"

Over the years, considerations along these lines grew into the C++ rule that it
was not sufficient to provide a feature, it had to be provided in an affordable
form. Most definitely, affordable was seen as meaning "affordable on
hardware common among developers" as opposed to "affordable to
researchers with high-end equipment" or "affordable in a couple of years
when hardware will be cheaper."

Stroustrup, Bjarne
Learning Standard C++ as a New Language
C/C++ Users Journal, May 1999

http://www.research.att.com/~bs/papers.html
http://www.research.att.com/~bs/cuj_code.html

This paper compares a few examples of simple C++ programs written in a
modern style using the standard library to traditional C-style solutions. It
argues briefly that lessons from these simple examples are relevant to large
programs. More generally, it argues for a use of C++ as a higher-level
language that relies on abstraction to provide elegance without loss of
efficiency compared to lower-level styles.

"I was appalled to find examples where my test programs ran twice as fast in
the C++ style compared to the C style on one system and only half as fast on
another. ... Better-optimized libraries may be the easiest way to improve both
the perceived and actual performance of Standard C++. Compiler
implementers work hard to eliminate minor performance penalties compared
with other compilers. I conjecture that the scope for improvements is larger in
the standard library implementations."

Sutter, Herb
Exceptional C++
Addison-Wesley, 2000.

This book includes a long discussion on minimizing compile-time
dependencies using compiler firewalls (the pimpl idiom), and how to
compensate for the space and run-time consequences.

Proceedings of the 2000 Workshop on C++ Template Programming
http://www.oonumerics.org/tmpw00

This paper describes a work in progress on a new C++ compiler. Type analysis is removed from the compiler and replaced with a type system library, which is treated as source code by the compiler.

"By making simple changes to the behavior of the partial evaluator, a wide range of compilation models is achieved, each with a distinct trade-off of compile-time, code size, and execution speed. ... This approach may solve several serious problems in compiling C++: it achieves separate compilation of templates, allows template code to be distributed in binary form by deferring template instantiation until run-time, and reduces the code bloat associated with templates."

Williams, Stephen

**Embedded Programming with C++**
http://www.usenix.org/publications/library/proceedings\ /coots97/williams.html

Describes experience in programming board-level components in C++, including a library of minimal run-time support functions portable to any board.

*We to this day face people telling us that C++ generates inefficient code that cannot possibly be practical for embedded systems where speed matters. The criticism that C++ leads to bad executable code is ridiculous, but at the same time accurate. Poor style or habits can in fact lead to awful results. On the other hand, a skilled C++ programmer can write programs that match or exceed the quality of equivalent C programs written by equally skilled C programmers.*

*The development cycle of embedded software does not easily lend itself to the trial-and-error style of programming and debugging, so a stubborn C++ compiler that catches as many errors as possible at compile-time significantly reduces the dependence on run-time debugging, executable run-time support and compile/download/test cycles.*

*This saves untold hours at the test bench, not to mention strain on PROM sockets.*

++ and (efficiency or performance)
Vendors of development tools often provide guidance on programming for maximum performance. Here are some of the documents available:

**Hewlett-Packard Corp.**

**CXperf User's Guide**

http://docs.hp.com/hpux/onlinedocs/B6323-96001/B6323-96001.html

This guide describes the CXperf Performance Analyser, an interactive run-time performance analysis tool for programs compiled with HP ANSI C (c89), ANSI C++ (aCC), Fortran 90 (f90), and HP Parallel 32-bit Fortran 77 (f77) compilers. This guide helps you prepare your programs for profiling, run the programs, and analyse the resulting performance data.

**IBM**

/a_doc_lib/aixbman/prftungd/toc.htm

An extensive discussion of performance issues in many areas, such as CPU use, disk I/O, and memory management, and even the performance effects of shared libraries. It discusses AIX tools available to measure performance, and the compiler options, which can be used to optimise an application for space or time. The chapter "Design and Implementation of Efficient Programs"

/a_doc_lib/aixbman/prftungd/desnimpl.htm

includes low-level recommendations such as these:

"Whenever possible, use int instead of char or short. In most cases, char and short data items take more instructions to manipulate. The extra instructions cost time, and, except in large arrays, any space that is saved by using the smaller data types is more than offset by the increased size of the executable. If you have to use a char, make it unsigned, if possible. A signed char takes another two instructions more than an unsigned char each time the variable is loaded into a register."

**Wind River Systems**

**Advanced Compiler Optimization Techniques**

This technical white paper discusses techniques for compiler optimizations in general, and more specifically those provided by the Wind River Systems “Diab” C++ compiler for embedded program development.
/*
 * Simple/naive measurements to give a rough idea of the relative cost of facilities related to OOP.

 I think this could be fooled/foiled by clever optimizers and by cache effects.

 Run at least three times to ensure that results are repeatable.

 Tests:

 virtual function
 global function called indirectly
 nonvirtual member function
 global function
 inline member function
 macro
 1st branch of MI
 2nd branch of MI
 call through virtual base
 call of virtual base function

dynamic cast
 two-level dynamic cast
 typeid()

call through pointer to member

call-by-reference
 call-by-value

 pass as pointer to function
 pass as function object

 not yet:

 co-variant return

 The cost of the loop is not measurable at this precision:
 see inline tests

 By default do 1000000 iterations to cout

 1st optional argument: number of iterations
 2nd optional argument: target file name

Appendix F: Sample C++
Implementation of Device Driver Code

This is preliminary example code for the C++-style portable interface to hardware:

```cpp
// proposed definition of <hardware>
// this is definition only

namespace std {
  namespace hardware {

    #include <stdint.h>:

    // the definitions of access_types' parameter types
    struct hw_base {
      enum access_mode {random, read_write, write, read};
      enum device_bus {device8, device16, device32, device64};
      enum byte_order {msb_low, msb_high};
      enum processor_bus {bus8, bus16, bus32, bus64};
      // only identifiers shall be present that are supported by
      // the underlying implementation! (Diagnostic required.)
      typedef _ul address_type;
    };

    // access specification types
    // only those access specifications shall be present
    // in an implementation that are supported by
    // the underlying hardware! (Diagnostic required.)
  }
}
```
// direct address for memory mapped registers and address know
// at compile time
template <typename ValueType,
    hw_base::access_mode mode, hw_base::address_type address, hw_base::device_bus devWidth, hw_base::byte_order endian, hw_base::processor_bus nativeWidth>
class direct_address
{
    public:
    typedef ValueType value_type;
    typedef _empty_type dynamic_data;
    // probably, we should also provide the mode info, but
    // how?
    enum { access_mode=mode }; // (would a type be a better
    // solution?)

    template <hw_base::address_type other_address> struct
    rebind
    {
        typedef direct_address<ValueType, mode, other_address, devWidth, endian, nativeWidth>
        other;
    };}

// dynamic address for memory mapped registers and address
// only know at run-time
template <typename ValueType,
    hw_base::access_mode mode, 
    typename AddressType, // UDT with implementation
    // defined semantics
    hw_base::device_bus devWidth, 
    hw_base::byte_order endian, 
    hw_base::processor_bus nativeWidth>
class dynamic_address
{
    public:
    typedef ValueType value_type;
    typedef AddressType dynamic_data;
    enum { access_mode=mode }; // (would a type be a better
    // solution?)
};
// the actual access interface

template <
    class AccessType,
    class DynamicData = typename AccessType::dynamic_data>

class register_access
{
public:
    typedef typename AccessType::value_type value_type;

    register_access();
    // for empty dynamic_data, the following ctor might not be
    // defined
    register_access(typename AccessType::dynamic_data const&);

    operator value_type() const;
    void operator=(value_type val) const;
    void operator|=(value_type val) const;
    void operator&=(value_type val) const;
    void operator^=(value_type val) const;

    struct _ref
    {
        explicit _ref(size_t) {}
        operator value_type() const;
        void operator=(value_type val) const;
        void operator|=(value_type val) const;
        void operator&=(value_type val) const;
        void operator^=(value_type val) const;
    };

    _ref operator[](size_t index) const
    {
        return _ref(index);
    }
};

} // namespace hardware

} // namespace std

This is preliminary example code for a sample C++ implementation for a simple
platform (watch out for line wrapping):

// proposed implementation of <hardware>

// The idea of this whole interface is to provide device driver
// implementers with a means to write a portable device driver for a
// specific hardware device (chip).
// If the device is attached to a different CPU, the way to access the
// hardware addresses might change, but the core of the device driver
// code should still be the same.
// To achieve this, the device driver implementer has to provide a
// different access type, but everything else remains stable.

namespace std {
    namespace hardware {
        // leading underscores in this implementation are there on
        // purpose, though they are ugly.
        // They make sure here that the use of these names are
        // reserved to the library implementer, and this is exactly
        // the role we have here.
// from #include <stdint.h>
typedef unsigned char uint8_t;
typedef unsigned short uint16_t;
typedef unsigned long uint32_t;
// there is no long long in C++ :-(
typedef unsigned long int _ul;
typedef unsigned char _uc;

// helper class for saving integral values as types
