A Proposal to Tweak Certain C++ Contextual Conversions

1 Introduction

The context in which a C++ expression appears often influences how the expression is evaluated, and therefore may impose requirements on the expression to ensure such evaluation is possible. For example, it is well-understood that an expression used in an `if`, `while`, or similar context must be convertible to `bool` so that the expression can be converted to `bool` during its evaluation. This conversion is termed *contextual*, and is set forth in \[conv\]/3.

In four cases, the current Working Draft (N3225) uses different language to specify an analogous context-dependent conversion. In those four contexts, when an operand is of class type, that type must have a "single non-explicit conversion function" to a suitable (context-specific) type. Here are the relevant excerpts (bold emphasis added), in order of occurrence:

- `[expr.new]/6`: "The *expression* in a `noptr-new-declarator` shall be of integral type, unscoped enumeration type, or a **class type for which a single non-explicit conversion function** to integral or unscoped enumeration type exists (12.3)."

- `[expr.delete]/1`: "The operand shall have a pointer to object type, or a **class type having a single non-explicit conversion function** (12.3.2) to a pointer to object type."

- `[expr.const]/5`: "If an expression of literal class type is used in a context where an integral constant expression is required, then that **class type shall have a single non-explicit conversion function** to an integral or enumeration type and that conversion function shall be `constexpr`."

- `[stmt.switch]/2`: "The condition shall be of integral type, enumeration type, or of a **class type for which a single non-explicit conversion function** to integral or enumeration type exists (12.3)."

Each excerpt cited above is followed by language stating or implying that the required conversion function will be used to convert an operand of class type and that the resulting converted value
will be used instead of the original. However, consider the small but very reasonable examples presented in the next section.

2 Motivating example

Listing 1 presents a modest template that wraps a value of arithmetic or pointer type \( T \), ensuring that the wrapped value will by default be initialized with \( T \)'s zero value. Note in particular the pair of conversion operators (lines 13-14), provided according to a well-established pattern allowing \texttt{const} and \texttt{non-const} objects to be treated differently.

Listing 2 shows a simple use of this template. We observe (verified with two modern compilers) that most expressions (\textit{e.g.} \texttt{*p}) have no compilation issue, but that the expression \texttt{delete p} produces diagnostics. More embarrassingly, the equivalent expression \texttt{delete (p+0)} is fine:

Listing 3 shows another use of this template. Here, too, the arithmetic, assignment, and comparison operations work fine, yet the simple expression \( i \) is embarrassingly ill-formed (although \( i+0 \) is not!) when used as the \texttt{switch} condition:

3 Discussion

The principal issue, in each of the four contexts cited in the Introduction, seems to lie in their common helpful but very strict requirement that limits a class to only one conversion operator
while allowing for the conversion of a value of the class’s type to a corresponding value of a type specified by the context. As shown earlier, such a limitation disallows straightforward code; the above examples must work around the restriction by otherwise uselessly adding zero (so that the conversion occurs in a different context that obeys different rules). We conclude from this that the current “single non-explicit conversion function” approach is unnecessarily strict, as it is less helpful than it could be and thus forces workarounds that seem silly.

Another concern is the scope of the qualifier “single” in the current wording. Must there be but a single conversion function in the class, or may there be several so long as a single one is appropriate to the context? The current language seems unclear on this point.

It is also unclear whether a conversion operator that produces a reference to an appropriate type is an appropriate conversion operator. (A question on this point was posted to the Core reflector, but went unanswered as of this writing.) Current compiler practice seems to admit such operators, but the current language seems not to.

Just as it does not allow a class to treat const and non-const objects of its type differently, the current approach also seems not always to admit a conversion function that may be declared in a base class. The concern here is the slight dichotomy in the current wording: Two cases speak of the class “having” an appropriate conversion function, while the other two require that the function “exists”. If the conversion function is in a base class, it “exists”, but the class at issue is not the one that “has” the function.

To address all these concerns, we recommend instead to use the proven approach typified by the term contextually converted to bool as defined in [conv]/3. We therefore propose a modest addition to [conv]/3 to define contextual conversion to other specified types, and then appeal to this new definition in rewording the Introduction’s four cited contexts.

Not only does the proposed change avoid the need for the embarrassing workaround shown above, it brings the benefit of more consistent behavior by eliminating four special cases for contextual conversions, aligning them with the rules for the C++0x contextual conversion to bool.

## 4 Proposed wording

The wording proposed in this section is based on that in N3225, with deleted text shown thus and new language like this.

### 4.1 Changes to [conv]

3 An expression e can be implicitly converted to a type T if and only if the declaration T t=e; is well-formed, for some invented temporary variable t (8.5).

— Certain language constructs require that an expression be converted to a Boolean value. An expression e appearing in such a context is said to be contextually converted to bool and is well-formed if and only if the declaration bool t(e); is well-formed, for some invented temporary variable t (8.5).

— Certain other language constructs require similar conversion, but to a value having one of a specified set of types appropriate to the construct. An expression e appearing in such a context is said to be contextually converted to a specified type and is well-formed if and only if the declaration T t=e; is well-formed, for some invented temporary variable t (8.5) of exactly one of the types T allowed by the context.

The effect of either any implicit conversion is the same as performing the declaration and initialization and then using the temporary variable as the result of the conversion. The result is an
lvalue if \( T \) is an lvalue reference type or an rvalue reference to function type (8.3.2), an xvalue if \( T \) is an rvalue reference to object type, and a prvalue otherwise. The expression \( e \) is used as a glvalue if and only if the initialization uses it as a glvalue.

Drafting notes: (1) The above wording uses a short bullet list to clarify the text's linguistic and technical structure by associating related sentences. Although we rather like the appearance of the resulting exposition, the list format is an optional part of the proposal. (2) We considered appending a Note to the first bullet to draw attention that it admits \texttt{explicit} conversion operators, but decided that would exceed the scope of this proposal.

4.2 Changes to \[\texttt{expr.new}\]

6 Every constant-expression in a \texttt{noptr-new-declarator} shall be an integral constant expression (5.19) and evaluate to a strictly positive value. The expression in a \texttt{noptr-new-declarator} shall be of integral type, unscoped enumeration type, or a class type for which a single non-explicit conversion function is contextually converted to integral or unscoped enumeration type exists (12.3). If the expression is of class type, the expression is converted by calling that conversion function, and the result of the conversion is used in place of the original expression. [\texttt{Example}: \ldots — end example ]

4.3 Changes to \[\texttt{expr.delete}\]

1 The \texttt{delete-expression} operator destroys a most derived object (1.8) or array created by a \texttt{new-expression}. \ldots The operand shall have a pointer to object type, or a class type having a single non-explicit conversion function (12.3.2) is contextually converted to a pointer to object type. The result has type \texttt{void}.\textsuperscript{79}

4.4 Changes to \[\texttt{expr.const}\]

5 If an expression of literal class type is used in a context where an integral constant expression is required, then that class type shall have a single non-explicit conversion function expression is contextually converted to an integral or enumeration type and that the applicable conversion function shall be \texttt{constexpr}. [\texttt{Example}: \ldots — end example ]

4.5 Changes to \[\texttt{stmt.switch}\]

2 The condition shall be of integral type, enumeration type, or of a class type for which a single non-explicit conversion function is contextually converted to integral or enumeration type exists (12.3). If the condition is of class type, the condition is converted by calling that conversion function, and the result of the conversion is used in place of the original condition for the remainder of this section. Integral promotions are performed. Any statement within the \texttt{switch} statement can be labeled with one or more case labels as follows: \ldots

5 Acknowledgments

Many thanks to the reviewers of early drafts of this paper for their helpful and constructive comments. We also acknowledge the Fermi National Accelerator Laboratory’s Computing Division, sponsor of our participation in the C++ standards effort, for its past and continuing support of our efforts to improve C++ for all our user communities.
