Abstract
This paper proposes the ability to declare multiple variables initialized from a `tuple` or struct, along the lines of:

```cpp
tuple<T1,T2,T3> f(/*...*/) { /*...*/ return {a,b,c}; }
auto {x,y,z} = f(); // x has type T1, y has type T2, z has type T3
```

This addresses the requests for support of returning multiple values, which has become a popular request lately. We already can return multiple values (e.g., via `tuple`) but lack a syntax to make it easy/elegant to use.

This paper contains no proposed wording. This is a discussion paper to determine EWG interest in the feature, and if there is interest to get direction for a follow-up paper with wording.

1. Motivation

Today, we allow multiple return values via `tuple` pretty nicely in function declarations and definitions:

```cpp
tuple<T1,T2,T3> f(/*...*/) {
    T1 a{}; T2 b{}; T3 c{};
    return {a,b,c};
}
```

We enable nice syntax at the call site too, if you have existing variables:

```cpp
T1 x; T2 y; T3 z;
tie(x,y,z) = f();
```

However, this has several drawbacks:

- It works only for separately declared variables.
- If those variables are of POD type, they may be uninitialized. This may violate reasonable coding rules.
- If they are non-PODs or initialized PODs, they may be initialized redundantly – first to a placeholder or default value (possibly using default construction) and then again to their intended value.
- Even default construction is often undesirable, for example if `f()` is an attempt to open a file stream and return the stream together with an outcome status. Being able to declare and initialize the variables at the same time would be much more direct and more natural to read.

What we could like is a syntax to declare and initialize variables:

```cpp
declare-and-tie(x,y,z) = f();
```

2. Proposal

We propose extending the local variable declaration syntax to allow:

- a single declaration that declares one or more local variables,
- that can have different types (and so must have a distinct syntax from the current multiple variable declaration syntax where all variables have the same type),
- whose types are always deduced (using `auto`, possibly `const`- or `&`-qualified),
- when assigned from a `std::tuple`, `std::pair`, or any class with all public non-static data members.

2.1 Basic syntax

For the basic syntax, we want to make the new form distinct enough from the current form that requires the variables to have the same type (e.g., `auto x = 1, y = 2, z = 3;`, or `auto x, y, z = f();` which initializes only `z` today).

There are several unused syntaxes available that we could use to express this case. Two major one are:

```cpp
auto (x,y,z) = f();  // Option 1: parentheses
auto {x,y,z} = f();  // Option 2: braces
```

Pending EWG direction, this paper will use Option 2 as a strawman syntax. It is more visually distinct from the existing syntax for declaring multiple variables which must be of the same type. Also, the `{x,y}` introduction syntax is used in concepts.
2.2 Direct and copy initialization

This paper proposes allowing both direct and copy initialization:

```
auto { list-of-comma-separated-variable-names } { expression };
auto { list-of-comma-separated-variable-names } = expression;
```

For simplicity the remaining examples will focus on copy initialization, but all examples apply to both forms.

2.3 Basic type deduction

The declaration

```
auto {x,y,z} = expression;
```

declares the variables x, y, and z, and deduces their respective types and initial values from the non-static data member of E, the type of expression, in declaration order. E must have the same number of data members (here three), and the data members must be accessible. The initialization of x, y, and z is performed as if x, y, and z were data members of E and we had written

```
E __e = expression;
```

to perform memberwise initialization. Note that for this construct to be efficient, the wording should be crafted to allow implementation latitude, such as copy elision.

A little more formally: Let E denote the type of the initializer expression. E shall be either a specialization of std::tuple, or a type whose non-static data members are all accessible and are declared in the same base class of E (E is considered a base class of itself for this purpose). The variables x, y, and z are initialized from a declaration-order traversal of the non-static data members of E, and their types are deduced from their initializers as if individually declared auto. If E has any non-static anonymous union member, then the first member of that union is selected for to initialize the corresponding variable. If that member is not the most recent active field of that union, the program is ill-formed (no diagnostic required). If E is a specialization of std::tuple then the Nth member is taken to be that member designated by __e.get<N>.

Specifically, E may be a tuple, pair, or user-defined type. For example:

```
tuple<T1,T2,T3> f();
auto {x,y,z} = f();    // types are: T1, T2, T3
map<int,string> mymap;
auto {iter, success} = mymap.insert(value);  // types are: iterator, bool
struct mystruct { int i; string s; double d; };     
mystruct s = { 1, "xyzzy"s, 3.14 };         
auto {x,y,z} = s;            // types are: int, string, double
```

2.4 Qualifying auto with a cv-qualifier

As with individual variable declarations, here auto can be cv-qualified. The declaration

```
auto const {x,y,z} = f();    // const T1, const T2, const T3
```

is as in 2.3 but declares x, y, and z to be const.
2.5 Qualifying auto with &
As with individual variable declarations, here auto can be &-qualified. If the initializer is an rvalue, then it must also be const-qualified, and results in lifetime extension of the returned tuple. Thus the declaration

```cpp
auto const& {x,y,z} = f();  // const T1&, const T2&, const T3&
```

is as in 2.3 but declares x, y, and z to be const&.

Further, the declaration

```cpp
auto& {x,y,z} = f();  // ERROR, illegal for an rvalue
```

is not legal for a returned rvalue, but can be correctly written by turning the rvalue into an lvalue:

```cpp
auto const& val = f();  // or just plain “auto” to copy by value
auto& {x,y,z} = val;  // ok, initializer is an lvalue
```

3. Q&A: Other options/extensions considered

3.1 Should this syntax support initialization from an initializer_list<T>?
We think the answer has to be no, primarily because the size of an initializer_list is dynamic whereas the list of variables to be defined is static.

3.2 Should this syntax support initialization from a braced-init-list?
For example:

```cpp
auto {x,y,z} = {1, “xyzzy”s, 3.14159};  // NOT proposed
```

We think the answer should be no. This would be trivial to add, but should be well motivated and we know of no use cases where this offers additional expressive power not already available (and with greater clarity) using individual variable declarations.

3.3 Should we also allow a non-declaration syntax without auto to replace tie() syntax?
For example:

```cpp
{x,y,z} = f();  // same as: tie(x,y,z) = ...
{iter, success} = mymap.insert(value);  // same as: tie(iter,success) = ...
```

We think the answer should be no. We know of no use cases where this is better than using std::tie, as noted in the comments. It would also complicate the grammar because { is already permitted in this position to begin a block, so we would need lookahead to disambiguate. (Using () parens is worse, because code like (iter, success) = expression; already has a meaning and in some cases might compile today.)

3.4 Should qualifying auto with && be supported?
We are undecided. Qualifying with && is for forwarding, which is usually for parameters. Valid local forwarding uses are rare… we know of only one, but it is notable, namely in range-for to forward the value to the loop body:

```cpp
for( auto&& {first,second} : mymap ) {  // NOT proposed
   // use first and second
 }
```
It seems this case could be better dealt by extending Stephan Lavavej’s proposal for range-for with a similar syntax to that supported in this proposal, rather than adding general support for &&.

### 3.5 Should the syntax be extended to allow `const/`-qualifying individual variables’ types?

For example:

```cpp
auto {& x, const y, const& z} = f(); // NOT proposed
```

We think the answer should be no. This is a simple feature intended to bind simple names to a structure’s components by value or by reference. We should avoid complication and keep the simple defaults simple.

We already have a way to spell the above, which also makes any lifetime extension explicit:

```cpp
auto const& val = f(); // or just plain “auto” to copy by value
T1& x = get<0>(val);
T2 const y = get<1>(val);
T3 const& z = get<2>(val);
```

Secondarily, we could be creating subtle lifetime surprises when the initializer is an rvalue:

- Should a single `const&` extend the lifetime of the whole tuple? The answer should probably be yes, but then this could cause surprises by silently extending lifetimes for the other values in the tuple.
- Should the use of non-const & be allowed? If we allow any `const&` to extend lifetime, then non-const & would also be safe as long as there was some other variable being declared using `const&`. But that would be inconsistent with the basic case, and create quirky declaration interactions.
- Should only `const`, but not & be allowed? That would avoid the above problems, but feels arbitrary.

### 3.6 Should this syntax support concepts? non-deduced (concrete) type(s)?

For example:

```cpp
string {x,y} = f(); // NOT proposed: same type
Iterator {x,y} = f(); // NOT proposed: same concept
something {int x, string& y} = f(); // NOT proposed: different types
something {Iterator it, bool b} = f(); // NOT proposed: different concepts
```

We think the answer should be no. This is a simple feature intended to bind simple names to a structure’s components by value or by reference. We should avoid complication and keep the simple defaults simple.

As noted in 3.5, we already have ways to spell all of the above. For example, the last line can already be spelled:

```cpp
auto const& val = f(); // or just plain “auto” to copy by value
Iterator it = get<0>(val);
bool b = get<1>(val);
```

The argument could be made that in other cases we do not have mandatory type deduction, so that for parameters and concepts you can choose among: specifying the exact type (no deduction); specifying a concept (constrained deduction); and specifying `auto` (unconstrained deduction). If we do not allow that here, we are breaking consistency for return value binding. We don’t think that argument holds, because the purpose of this feature is to supply a simple default that you can already write out by hand. We do not need to burden a targeted feature with ornamentation to become a second (and ornate) way to spell something we can spell already; indeed, that would be missing the point of adding a simple default.
Finally, allowing specific concepts or types would be feature creep. The purpose of the feature is to bind new names to the values that are already there. Even replacing `auto` with a concept or type as in the first group of lines changes the meaning, because in the proposal `auto{x,y}` can deduce different types whereas presumably the concept or type must apply to all variables. This will nearly always be wrong, and people will want to mention the concept and type names on the individual components, leading right back to 3.5 with the same observations noted there, including that we already have a way to spell those things.

### 3.7 Should there be a way to explicitly ignore variables?

The motivation would be to silence compiler warnings about unused variables.

We think the answer should be “not yet.” This is not motivated by use cases (silencing compiler warnings is a motivation, but it is not a use case per se), and is best left until we can revisit this in the context of a more general pattern matching proposal where this should fall out as a special case.

Symmetry with `std::tie`, which uses `std::ignore` in expression, would suggest using something like a `std::ignore_t` (since this is a declaration, not an expression):

```cpp
tuple<T1,T2,T3> f();
auto {x, std::ignore_t, z} = f(); // NOT proposed: ignore second element
```

However, this feels awkward.

Anticipating pattern matching in the language could suggest a wildcard like `_` or `*`, but since we do not yet have pattern matching it is premature to pick a syntax that we know will be compatible. This is a pure extension that can wait to be considered with pattern matching.

### 3.8 Should there be support for recursive destructuring?

For example:

```cpp
std::tuple<T1, std::pair<T2, T3>, T4> f();
auto { w, {x, y}, z } = f(); // NOT proposed: types are T1, T2, T3, T4
```

This could be a future extension, following experience in languages like Python.
