Revision History

This document supersedes P0876R5.

Changes since P0876R5:

- std::unwind_exception removed: stack unwinding must be performed by platform facilities.
- fiber_context::can_resume_from_any_thread() renamed to can_resume_from_this_thread().
- fiber_context::valid() renamed to empty() with inverted sense.
- Material has been added concerning the top-level wrapper logic governing each fiber.

The change to unwinding fiber stacks using an anonymous foreign exception not catchable by C++ try / catch blocks is in response to deep discussions in Kona 2019 of the surprisingly numerous problems surfaced by using an ordinary C++ exception for that purpose.

Further information about the specific mechanism can be found in stack unwinding et ff.

Problems resolved by discarding std::unwind_exception in favor of a non-C++ foreign exception:
When unwinding a fiber stack, it is essential to know the subsequent fiber to resume. std::unwind_exception therefore bound a std::fiber_context. std::fiber_context is move-only. But C++ exceptions must be copyable.

It was possible to catch and discard std::unwind_exception, with problematic consequences for its bound std::fiber_context. The new mechanism does not permit that.

Similarly, it used to be possible to catch std::unwind_exception but not rethrow it.

If we attempted to address the problem above by introducing a std::unwind_exception operation to extract the bound std::fiber_context, it became possible to rethrow the exception with an empty (moved-from) std::fiber_context instance.

Throwing a C++ exception during C++ exception unwinding terminates the program. But destroying a std::fiber_context no longer causes a C++ exception to be thrown.

It is no longer possible to capture std::unwind_exception with std::exception_ptr and migrate it to a different fiber – or a different thread.

We have also addressed what happens when a std::fiber_context instance representing main(), or the default fiber on a std::thread, is destroyed.

abstract

This paper addresses concerns, questions and suggestions from the past meetings. The proposed API supersedes the former proposals N3985, P0099R1, P0534R3 and P0876R5.

Because of name clashes with coroutine from coroutine TS, execution context from executor proposals and continuation used in the context of future::then(), the committee has indicated that fiber is preferable. However, given the foundational, low-level nature of this proposal, we choose fiber_context, leaving the term fiber for a higher-level facility built on top of this one.

The minimal API enables stackful context switching without the need for a scheduler. The API is suitable to act as building-block for high-level constructs such as stackful coroutines as well as cooperative multitasking (aka user-land/green threads that incorporate a scheduling facility).

Informally within this proposal, the term fiber is used to denote the lightweight thread of execution launched and represented by the first-class object std::fiber_context.

control transfer mechanism

According to the literature, coroutine-like control-transfer operations can be distinguished into the concepts of symmetric and asymmetric operations.

symmetric fiber A symmetric fiber provides a single control-transfer operation. This single operation requires that the control is passed explicitly between the fibers.

```
1 fiber_context* pf1;
2 fiber_context f4{[&pf1] { 
3 pf1->resume();
4 }};
5 fiber_context f3{[&f4] { 
6 f4.resume();
7 }};
8 fiber_context f2{[&f3] { 
9 f3.resume();
10 }};
```
In the pseudo-code example above, a chain of fibers is created.

Control is transferred to fiber $f_1$ at line 15 and the lambda passed to constructor of $f_1$ is entered. Control is transferred from fiber $f_1$ to $f_2$ at line 12 and from $f_2$ to $f_3$ (line 9) and so on. Fiber $f_4$ itself transfers control directly back to fiber $f_1$ at line 3.

**asymmetric fiber**  Two control-transfer operations are part of asymmetric fiber’s interface: one operation for resuming (`resume()`) and one for suspending (`suspend()`) the fiber. The suspending operation returns control back to the calling fiber.

In the pseudo code above execution control is transferred to fiber $f_1$ at line 16. Fiber $f_1$ resumes fiber $f_2$ at line 13 and so on. At line 2 fiber $f_4$ calls its suspend operation `self::suspend()`. Fiber $f_4$ is suspended and $f_3$ resumed. Inside the lambda, $f_3$ returns from $f_4.resume()$ and calls `self::suspend()` (line 6). Fiber $f_3$ gets suspended while $f_2$ will be resumed and so on ...

The asymmetric version needs $N-1$ more fiber switches than the variant using symmetric fibers.

The asymmetric version needs $N-1$ more fiber switches than the variant using symmetric fibers.

---

**While asymmetric fibers establish a caller-callee relationship (strongly coupled), symmetric fibers operate as siblings (loosely coupled).**

Symmetric fibers represent independent units of execution, making symmetric fibers a suitable mechanism for concurrent programming. Additionally, constructs that produce sequences of values (generators) are easily constructed out of two symmetric fibers (one represents the caller, the other the callee).

Asymmetric fibers incorporate additional fiber switches as shown in the pseudo code above. It is obvious that for a broad range of use cases, asymmetric fibers are less efficient than their symmetric counterparts.

Additionally, the calling fiber must be kept alive until the called fiber terminates. Otherwise the call of `suspend()` will be undefined behaviour (where to transfer execution control to?).

Symmetric fibers are more efficient, have fewer restrictions (no caller-callee relationship) and can be used to create a wider set of applications (generators, cooperative multitasking, backtracking ...).
std::fiber_context as a first-class object

Because the symmetric control-transfer operation requires explicitly passing control between fibers, fibers must be expressed as first-class objects.

Fibers exposed as first-class objects can be passed to and returned from functions, assigned to variables or stored into containers. With fibers as first-class objects, a program can explicitly control the flow of execution by suspending and resuming fibers, enabling control to pass into a function at exactly the point where it previously suspended.

Symmetric control-transfer operations require fibers to be first-class objects. First-class objects can be returned from functions, assigned to variables or stored into containers.

encapsulating the stack

Each fiber is associated with a stack and is responsible for managing the lifespan of its stack (allocation at construction, deallocation when fiber terminates). The RAII-pattern should apply.

Copying a std::fiber_context must not be permitted!

If a std::fiber_context were copyable, then its stack with all the objects allocated on it must be copied too. That presents two implementation choices.

- One approach would be to capture sufficient metadata to permit object-by-object copying of stack contents. That would require dramatically more runtime information than is presently available – and would take considerably more overhead than a coder might expect. Naturally, any one move-only object on the stack would prohibit copying the entire stack.

- The other approach would be a bytewise copy of the memory occupied by the stack. That would force undefined behaviour if any stack objects were RAII-classes (managing a resource via RAII pattern). When the first of the fiber copies terminates (unwinds its stack), the RAII class destructors will release their managed resources. When the second copy terminates, the same destructors will try to doubly-release the same resources, leading to undefined behavior.

A fiber API must:

- encapsulate the stack
- manage lifespan of an explicitly-allocated stack: the stack gets deallocated when std::fiber_context goes out of scope
- prevent accidentally copying the stack

Class std::fiber_context must be moveable-only.

invalidation at resumption

The framework must prevent the resumption of an already running or terminated (computation has finished) fiber.

Resuming an already running fiber will cause overwriting and corrupting the stack frames (note, the stack is not copyable). Resuming a terminated fiber will cause undefined behaviour because the stack might already be unwound (objects allocated on the stack were destroyed or the memory used as stack was already deallocated).

As a consequence each call of resume() will empty the std::fiber_context instance, therefore no instance of std::fiber_context represents the currently-running fiber.

Whether or not a std::fiber_context is empty can be tested with member function operator bool().

To make this more explicit, functions resume(), resume_with(), resume_from_any_thread() and resume_from_any_thread_with() are rvalue-reference qualified.

The essential points:

*resource acquisition is initialisation
regardless of the number of std::fiber_context declarations, exactly one std::fiber_context instance represents each suspended fiber

no std::fiber_context instance represents the currently-running fiber

Section solution: avoiding non-const global variables and undefined behaviour describes how an instance of std::fiber_context is synthesized from the active fiber that suspends.

<table>
<thead>
<tr>
<th>A fiber API must:</th>
</tr>
</thead>
<tbody>
<tr>
<td>• prevent accidentally resuming a running fiber</td>
</tr>
<tr>
<td>• prevent accidentally resuming a terminated (computation has finished) fiber</td>
</tr>
<tr>
<td>• resume(), resume_with(), resume_from_any_thread() and resume_from_any_thread_with() are rvalue-reference qualified to bind on rvalues only</td>
</tr>
</tbody>
</table>

problem: avoiding non-const global variables and undefined behaviour

According to C++ core guidelines, non-const global variables should be avoided: they hide dependencies and make the dependencies subject to unpredictable changes.

Global variables can be changed by assigning them indirectly using a pointer or by a function call. As a consequence, the compiler can’t cache the value of a global variable in a register, degrading performance (unnecessary loads and stores to global memory especially in performance critical loops).

Accessing a register is one to three orders of magnitude faster than accessing memory (depending on whether the cache line is in cache and not invalidated by another core; and depending on whether the page is in the TLB).

The order of initialisation (and thus destruction) of static global variables is not defined, introducing additional problems with static global variables.

A library designed to be used as building block by other higher-level frameworks should avoid introducing global variables. If this API were specified in terms of internal global variables, no higher level layer could undo that: it would be stuck with the global variables.

switch back to main() by returning

Switching back to main() by returning from the fiber function has two drawbacks: it requires an internal global variable pointing to the suspended main() and restricts the valid use cases.

```cpp
int main() {
    fiber_context f[{...]
    // switch to 'main()' only by returning
    });
    f.resume(); // resume 'f'
    return 0;
}
```

For instance the generator pattern is impossible because the only way for a fiber to transfer execution control back to main() is to terminate. But this means that no way exists to transfer data (sequence of values) back and forth between a fiber and main().

switching to main() only by returning is impractical because it limits the applicability of fibers and requires an internal global variable pointing to main().

static member function returns active std::fiber_context

P0099R0 introduced a static member function (execution_context::current()) that returned an instance of the active fiber. This allows passing the active fiber m (for instance representing main()) into the fiber l via lambda capture. This mechanism enables switching back and forth between the fiber and main(), enabling a rich set of applications (for instance generators).
int main(){
    int a;
    fiber_context m=fiber_context::current(); // get active fiber
    fiber_context f{[]{
        a=0;
        int b=1;
        for(;;){
            m=m.resume(); // switch to 'main()
            int next=a+b;
            a=b;
            b=next;
        }
    }};
    for(int j=0; j<10; ++j) {
        f=f.resume(); // resume 'f'
        std::cout << a << " ";
    }
    return 0;
}

But this solution requires an internal global variable pointing to the active fiber and some kind of reference counting. Reference counting is needed because fiber_context::current() necessarily requires multiple instances of std::fiber_context for the active fiber. Only when the last reference goes out of scope can the fiber be destroyed and its stack deallocated.

fiber_context f1=fiber_context::current();
fiber_context f2=fiber_context::current();
assert(f1==f2); // f1 and f2 point to the same (active) fiber

Additionally a static member function returning an instance of the active fiber would violate the protection requirements of sections encapsulating the stack and invalidation at resumption. For instance you could accidentally attempt to resume the active fiber by invoking resume().

fiber_context m=fiber_context::current();
m.resume(); // tries to resume active fiber == UB

A static member function returning the active fiber requires a reference counted global variable and does not prevent accidentally attempting to resume the active fiber.

solution: avoiding non-const global variables and undefined behaviour

The avoid non-const global variables guideline has an important impact on the design of the std::fiber_context API!

synthesizing the suspended fiber  The problem of global variables or the need for a static member function returning the active fiber can be avoided by synthesizing the suspended fiber and passing it into the resumed fiber (as parameter when the fiber is first started, or returned from resume()).

void foo(){
    fiber_context f{[](fiber_context&& m){
        m=std::move(m).resume(); // switch to 'foo()'
        m=std::move(m).resume(); // switch to 'foo()'
        ...
    }};
    f=std::move(f).resume(); // start 'f'
    f=std::move(f).resume(); // resume 'f'
}
In the pseudo-code above the fiber \( f \) is started by invoking its member function \( \text{resume()} \) at line 7. This operation suspends \( \text{foo} \), empties instance \( f \) and synthesizes a new \( \text{std::fiber_context m} \) that is passed as parameter to the lambda of \( f \) (line 2).

Invoking \( m.\text{resume()} \) (line 3) suspends the lambda, empties \( m \) and synthesizes a \( \text{std::fiber_context} \) that is returned by \( f.\text{resume()} \) at line 7. The synthesized \( \text{std::fiber_context} \) is assigned to \( f \). Instance \( f \) now represents the suspended fiber running the lambda (suspended at line 3). Control is transferred from line 3 (lambda) to line 7 (\( \text{foo()} \)).

Call \( f.\text{resume()} \) at line 8 empties \( f \) and suspends \( \text{foo()} \) again. A \( \text{std::fiber_context} \) representing the suspended \( \text{foo()} \) is synthesized, returned from \( m.\text{resume()} \) and assigned to \( m \) at line 3. Control is transferred back to the lambda and instance \( m \) represents the suspended \( \text{foo()} \).

Function \( \text{foo()} \) is resumed at line 4 by executing \( m.\text{resume()} \) so that control returns at line 8 and so on ... 

**Class symmetric_coroutine<>::yield_type from N3985** is not equivalent to the synthesized \( \text{std::fiber_context} \). \( \text{symmetric_coroutine<>::yield_type} \) does not represent the suspended context, instead it is a special representation of the same coroutine. Thus \( \text{main()} \) or the current thread’s entry-function can not be represented by \( \text{yield_type} \) (see next section representing \( \text{main()} \) and thread’s entry-function as fiber).

Because \( \text{symmetric_coroutine<>::yield_type()} \) yields back to the starting point, i.e. invocation of \( \text{symmetric_coroutine<>::call_type::operator()} \), both instances (\( \text{call_type} \) as well as \( \text{yield_type} \)) must be preserved. Additionally the caller must be kept alive until the called coroutine terminates or UB happens at resumption.

This API is specified in terms of passing the suspended \( \text{std::fiber_context} \). A higher level layer can hide that by using private variables.

**representing \( \text{main()} \) and thread’s entry-function as fiber**  
As shown in the previous section a synthesized fiber is created and passed into the resumed fiber as an instance of \( \text{std::fiber_context} \).

```cpp
int main(){
    fiber_context f[]{[](fiber_context&& m){
        m=std::move(m).resume(); // switch to 'main'
        ... 
    });
    f=std::move(f).resume(); // resume 'f'
    return 0;
}
```

The mechanism presented in this proposal describes switching between stacks: each fiber has its own stack. The stacks of \( \text{main()} \) and explicitly-launched threads are not excluded; these can be used as targets too.

Thus every program can be considered to consist of fibers – some created by the OS (\( \text{main()} \) stack; each thread’s initial stack) and some created explicitly by the code.

This is a nice feature because it allows (the stacks of \( \text{main()} \) and each thread’s entry-function to be represented as fibers. A \( \text{std::fiber_context} \) representing \( \text{main()} \) or a thread’s entry-function can be handled like an explicitly created \( \text{std::fiber_context} \): it can passed to and returned from functions or stored in a container. When called on such an instance, \( \text{can_resume_from_this_thread()} \) indicates whether it is valid to call \( \text{resume_from_any_thread()} \) or \( \text{resume_from_any_thread_with()} \) on that instance.

In the code snippet above the suspended \( \text{main()} \) is represented by instance \( m \) and could be stored in containers or managed just like \( f \) by a scheduling algorithm.

**The proposed fiber API allows representing and handling \( \text{main()} \) and the current thread’s entry-function by an instance of \( \text{std::fiber_context} \) in the same way as explicitly created fibers.**

**fiber returns (terminates)**  
When a fiber returns (terminates), what should happen next? Which fiber should be resumed next? The only way to avoid internal global variables that point to \( \text{main()} \) is to explicitly return a non-empty \( \text{std::fiber_context} \) instance that will be resumed after the active fiber terminates.

```cpp
1 int main(){
2     fiber_context f[]{[](fiber_context&& m){
3         return std::move(m); // resume 'main()' by returning 'm'
4     }};
5 }
```
In line 5 the fiber is started by invoking `resume()` on instance `f`. `main()` is suspended and an instance of type `fiber_context` is synthesized and passed as parameter `m` to the lambda at line 2. The fiber terminates by returning `m`. Control is transferred to `main()` (returning from `f.resume()` at line 5) while fiber `f` is destroyed.

In a more advanced example another `std::fiber_context` is used as return value instead of the passed in synthesized fiber.

```cpp
int main(){
    fiber_context m;
    fiber_context f1{[&](fiber_context&& f){
        std::cout << "f1: entered first time" << std::endl;
        assert(!f);
        return std::move(m); // resume (main-)fiber that has started 'f2'
    }};
    fiber_context f2{[&](fiber_context&& f){
        std::cout << "f2: entered first time" << std::endl;
        m=std::move(f); // preserve 'f' (== suspended main())
        return std::move(f1);
    }};
    std::move(f2).resume();
    std::cout << "main: done" << std::endl;
    return 0;
}
```

Output:
```
f2: entered first time
f1: entered first time
main: done
```
std::cout << "f3 ";
std::move(f1).resume();
}
return {};
}

f2=fiber_context{[&]{fiber_context&& f}->fiber_context{
   f1=std::move(f);
   for(;;){
      std::cout << "f2 ";
      std::move(f3).resume();
   }
   return {};
}};
f1=fiber_context{[&]{fiber_context&& /*main*/}->fiber_context{
   for(;;){
      std::cout << "f1 ";
      std::move(f2).resume();
   }
   return {};
}):
std::move(f1).resume();
return 0;
}

output:
f1 f2 f3 f1 f3 f1 f3 f1 f3 ...

In this pseudo-code the std::fiber_context object is implicitly updated.
The example creates a circle of fibers: each fiber prints its name and resumes the next fiber (f1 -> f2 -> f3 -> f1 -> ...).

Fiber f1 is started at line 26. The synthesized std::fiber_context main passed to the resumed fiber is not used (control flow cycles through the three fibers).* The for-loop prints the name f1 and resumes fiber f2. Inside f2’s for-loop the name is printed and f3 is resumed. Fiber f3 resumes fiber f1 at line 7. Inside f1 control returns from f2.resume(). f1 loops, prints out the name and invokes f2.resume(). But this time fiber f3 instead of f2 is resumed. This is caused by the fact the instance f2 gets the synthesized std::fiber_context of f3 implicitly assigned. Remember that at line 7 fiber f3 gets suspended while f1 is resumed through f1.resume().

This problem can be solved by returning the synthesized std::fiber_context from resume(), resume_with(), resume_from_any_thread() or resume_from_any_thread_with().

```
int main(){
   fiber_context f1,f2,f3;
   f3=fiber_context{[&]{fiber_context&& f}->fiber_context{
      f2=std::move(f);
      for(;;){
         std::cout << "f3 ";
         f2=std::move(f1).resume();
      }
      return {};
   }};
   f2=fiber_context{[&]{fiber_context&& f}->fiber_context{
      f1=std::move(f);
      for(;;){
         std::cout << "f2 ";
         f1=std::move(f3).resume();
      }
      return {};
   }};
   f1=fiber_context{[&]{fiber_context&& /*main*/}->fiber_context{
      for(;;){
      
   }
```
std::cout << "f1 ";
f3=std::move(f2).resume();
}
return ();
});
std::move(f1).resume();
return 0;
}

output:
f1 f2 f3 f1 f2 f3 f1 f2 f3 ...

In the example above the synthesized std::fiber_context returned by resume() is move-assigned to the invoking std::fiber_context instance (that has resumed the current fiber).

The synthesized std::fiber_context must be returned from resume(), resume_with(), resume_from_any_thread() and resume_from_any_thread_with() in order to prevent changing the identity of the fiber.

If the overall control flow isn’t known, member functions resume_with() or resume_from_any_thread_with() (see section inject function into suspended fiber) can be used to assign the synthesized std::fiber_context to the correct std::fiber_context instance (the caller).

```cpp
class filament{
private:
    fiber_context f_;  

public:
    ... 
    void resume_next( filament& fila){
        std::move(fila.f_).resume_with([this](fiber_context&& f)->fiber_context{
            f_=std::move(f);
            return {};
        })
    }
};
```

Picture a higher-level framework in which every fiber can find its associated filament instance, as well as others. Every context switch must be mediated by passing the target filament instance to the running fiber’s resume_next().

Running fiber A has an associated filament instance filamentA, whose std::fiber_context f_ is empty – because fiber A is running.

Desiring to switch to suspended fiber B (with associated filament filamentB), running fiber A calls filamentA.resume_next(filamentB).

resume_next() calls filamentB.f_.resume_with(<lambda>). This empties filamentB.f_ – because fiber B is now running.

The lambda binds &filamentA as this. Running on fiber B, it receives a std::fiber_context instance representing the newly-suspended fiber A as its parameter f. It moves that std::fiber_context instance to filamentA.f_.

The lambda then returns a default-constructed (therefore empty) std::fiber_context instance. That empty instance is returned by the previously-suspended resume_with() call in filamentB.resume_next() – which is fine because resume_next() drops it on the floor anyway.

Thus, the running fiber’s associated filament::f_ is always empty, whereas the filament associated with each suspended fiber is continually updated with the std::fiber_context instance representing that fiber.

* Boost.Fiber uses this pattern for resuming user-land threads.
It is not necessary to know the overall control flow. It is sufficient to pass a reference/pointer of the caller (fiber that gets suspended) to the resumed fiber that move-assigns the synthesized `std::fiber_context` to caller (updating the instance).

**inject function into suspended fiber**

Sometimes it is useful to inject a new function (for instance, to throw an exception or assign the synthesized fiber to the caller as described in returning synthesized `std::fiber_context` instance from `resume()`) into a suspended fiber. For this purpose `resume_with(Fn&& fn)` (or `resume_from_any_thread_with()`) may be called, passing the function `fn()` to execute.

```cpp
fiber_context f{[](fiber_context&& caller){
  // ...
  std::move(caller).resume();
  // ...
});
fiber_context fn(fiber_context&&);
fn = std::move(f).resume();
// ...
std::move(f).resume_with(fn);
```

The `resume_with()` call at line 11 injects function `fn()` into fiber `f` as if the `resume()` call at line 3 had directly called `fn()`.

Like an `entry-function` passed to `std::fiber_context, fn()` must accept `std::fiber_context&&` and return `std::fiber_context`. The `std::fiber_context` instance returned by `fn()` will, in turn, be returned to `f`'s lambda by the `resume()` at line 3.

Suppose that code running on the program’s main fiber calls `resume()` (line 12 below), thereby entering the first lambda shown below. This is the point at which `m` is synthesized and passed into the lambda at line 2.

Suppose further that after doing some work (line 4), the lambda calls `m.resume()`, thereby switching back to the main fiber. The lambda remains suspended in the call to `m.resume()` at line 5.

At line 18 the main fiber calls `f.resume_with()` where the passed lambda accepts `fiber_context&`. That new lambda is called on the fiber of the suspended lambda. It is as if the `m.resume()` call at line 8 directly called the second lambda.

The function passed to `resume_with()` has almost the same range of possibilities as any function called on the fiber represented by `f`. Its special invocation matters when control leaves it in either of two ways:

1. If it throws an exception, that exception unwinds all previous stack entries in that fiber (such as the first lambda’s) as well, back to a matching `catch` clause.

2. If the function returns, the returned `std::fiber_context` instance is returned by the suspended `m.resume()` (or `resume_with()`, or `resume_from_any_thread()`, or `resume_from_any_thread_with()`) call.

```cpp
int data = 0;
fiber_context f{[](fiber_context&& m){
  std::cout << "f1: entered first time: " << data << std::endl;
  data+=1;
  m=std::move(m).resume();
  std::cout << "f1: entered second time: " << data << std::endl;
  data+=1;
  m=std::move(m).resume();
  std::cout << "f1: entered third time: " << data << std::endl;
  return std::move(m);
}};
f=std::move(f).resume();
std::cout << "f1: returned first time: " << data << std::endl;
```

*As stated in exceptions, if there is no matching `catch` clause in that fiber, `std::terminate()` is called.
data+=1;
f=std::move(f).resume();
std::cout << "f1: returned second time: " << data << std::endl;
data+=1;
f=std::move(f).resume_with([&data](fiber_context&& m) {
    std::cout << "f2: entered: " << data << std::endl;
data=-1;
    return std::move(m);
});
std::cout << "f1: returned third time" << std::endl;

output:
f1: entered first time: 0
f1: returned first time: 1
f1: entered second time: 2
f1: returned second time: 3
f2: entered: 4
f1: entered third time: -1
f1: returned third time

The f.resume_with(<lambda>) call at line 18 passes control to the second lambda on the fiber of the first lambda.

As usual, resume_with() synthesizes a std::fiber_context instance representing the calling fiber, passed into the lambda as m. This particular lambda returns m unchanged at line 21; thus that m instance is returned by the resume() call at line 8.

Finally, the first lambda returns at line 10 the m variable updated at line 8, switching back to the main fiber.

One case worth pointing out is when you call resume_with() (or resume_from_any_thread_with()) on a std::fiber_context that has not yet been resumed for the first time:

```cpp
topfunc(fiber_context&& prev);
injected(fiber_context&& prev);
```

// topfunc() has not yet been entered
std::move(f).resume_with(injected);

In this situation, injected() is called with a std::fiber_context instance representing the caller of resume_with(). When injected() eventually returns that (or some other) std::fiber_context instance, the returned std::fiber_context instance is passed into topfunc() as its prev parameter.

Member functions resume_with() and resume_from_any_thread_with() allow you to inject a function into a suspended fiber.

### passing data between fibers

Data can be transferred between two fibers via global pointer, a calling wrapper (like std::bind) or lambda capture.

```cpp
int i=1;
std::fiber_context lambda{[&i](fiber_context&& caller) {
    std::cout << "inside lambda,i==" << i << std::endl;
i+=1;
caller=std::move(caller).resume();
    return std::move(caller);
}};
lambda=std::move(lambda).resume();
std::cout << "i==" << i << std::endl;
lambda=std::move(lambda).resume();
```

output:
inside lambda,i==1
The `resume()` call at line 8 enters the lambda and passes 1 into the new fiber. The value is incremented by one, as shown at line 4. The expression `caller.resume()` at line 5 resumes the original context (represented within the lambda by `caller`).

The call to `lambda.resume()` at line 10 resumes the lambda, returning from the `caller.resume()` call at line 5. The `std::fiber_context` instance `caller` emptied by the `resume()` call at line 5 is replaced with the new instance returned by that same `resume()` call.

Finally the lambda returns (the updated) `caller` at line 6, terminating its context.

Since the updated `caller` represents the fiber suspended by the call at line 10, control returns to `main()`.

However, since context `lambda` has now terminated, the updated `lambda` is empty. Its `operator bool()` returns `false`.

| Using lambda capture is the preferred way to transfer data between two fibers; global pointers or a calling wrapper (such as `std::bind`) are alternatives. |

**termination**

There are a few different ways to terminate a given fiber without terminating the whole process, or engaging undefined behavior.

When a `std::fiber_context` instance is constructed with an `entry-function`, its new stack is initialized with the frame of an implicit top-level function that marks the end of the stack. `std::unwind_fiber()` unwinds the stack back to that top-level function, which resumes the `std::fiber_context` passed to `std::unwind_fiber()`.

Therefore, any of the following will gracefully terminate a fiber:

- Cause its `entry-function` to return a non-empty `std::fiber_context`.
- From within the fiber you wish to terminate, call `std::unwind_fiber()` with a non-empty `std::fiber_context`. That fiber will be resumed when the active fiber terminates.
- Call `fiber_context::resume_with(unwind_fiber)`. **This is what `~fiber_context()` does. Since `std::unwind_fiber()` accepts a `std::fiber_context`, and since `resume_with()` synthesizes a `std::fiber_context` representing its caller and passes it to the subject function, this terminates the fiber referenced by the original `std::fiber_context` instance and then resumes the caller.**
- Engage `~fiber_context()`: switch to some other fiber, which will receive a `std::fiber_context` instance representing the current fiber. Make that other fiber destroy the received `std::fiber_context` instance.

The above are all equivalent: stack variables are properly destroyed, since the stack is unwound. (See stack unwinding.)

In an environment that forbids exceptions, every `std::fiber_context` you launch must terminate gracefully by returning from its top-level function. You may not call `std::unwind_fiber()`. You may not call `~fiber_context()`, explicitly or implicitly, on a non-empty `std::fiber_context` instance. With these restrictions, it is possible to use the `std::fiber_context` facility without exception support.

When an explicitly-launched fiber’s `entry-function` returns a non-empty `std::fiber_context` instance, the running fiber is terminated. Control switches to the fiber indicated by the returned `std::fiber_context` instance. The `entry-function` may return (switch to) any reachable non-empty `std::fiber_context` instance – it need not be the instance originally passed in, or an instance returned from any of the `resume()` family of methods.

Calling `resume()` means: “Please switch to the indicated fiber; I am suspending; please resume me later.”

Returning a particular `std::fiber_context` means: “Please switch to the indicated fiber; and by the way, I am done.”

The last fiber on a particular thread has no non-empty `std::fiber_context` to return. For this reason, returning an empty `std::fiber_context` instance (`operator bool()` returns `false`) terminates the calling thread. This is true whether or not the thread’s default fiber (see Explicit Fiber vs. Implicit Fiber) has terminated.
**Stack Unwinding**

Stack unwinding caused by an exception, thread termination or fiber destruction exits functions on that stack without executing a `return` statement. Local variables that go out of scope may have destructors that must be called. The implementation must walk the stack and call the destructor for each object in every such stack frame.

The C++ standard does not define how exception handling is implemented. Stack unwinding differs among different systems. The process of stack unwinding is described in the system ABI, for instance:

- `.eh_frame/personality` routine on SYS V AMD64 ABI (de facto standard among Unix-like operating systems)
- `RUNTIME_FUNCTION/UNWIND_INFO` on x64 Windows
- `.pdata/.xdata` on ARM64 Windows

**SYS V AMD64 Unwind Library** is based on DWARF CFI (call frame information) that are stored in the `.eh_frame` section. Unwinding happens under following circumstances:

- A C++ exception has been thrown
- unwinding is forced by an external agent (longjmp for instance)

`_Unwind_ForcedUnwind()` takes a `foreign exception` (non-C++ exception; for instance Java or GO) and walks the stack frame by frame inspecting the `unwind tables` for cleanup functions (for instance destructors of local variables) and catch blocks.

`_Unwind_ForcedUnwind()` calls a `personality routine` (_gxx_personality_v0() for GCC). `_Unwind_ForcedUnwind()` takes a stop function that controls the termination of the unwinding (reaching end of stack for fibers). The stop function intercepts calls to the personality routine, letting the external agent override the defaults of the stack frame’s personality routine. When the destination frame (last frame on fiber stack) is reached, control jumps back to the caller without further popping the stack.

The code snippet below is a proof of concept available at Boost.Context branch p0876r6.

```cpp
constexpr _Unwind_Exception_Class __gxx_fiber_exception_class
= ((((((((_Unwind_Exception_Class) 'G'
<< 8 | (_Unwind_Exception_Class) 'N')
<< 8 | (_Unwind_Exception_Class) 'U')
<< 8 | (_Unwind_Exception_Class) 'F')
<< 8 | (_Unwind_Exception_Class) 'I')
<< 8 | (_Unwind_Exception_Class) 'B')
<< 8 | (_Unwind_Exception_Class) 'E')
<< 8 | (_Unwind_Exception_Class) 'R');

#define __GXX_INIT_FIBER_EXCEPTION_CLASS(c) c = __gxx_fiber_exception_class

class foreign_unwind_ex : public _Unwind_Exception {
private:
static void fiber_unwind_cleanup(_Unwind_Reason_Code code, _Unwind_Exception *exc) {
    // We only want to be called through _Unwind_DeleteException.
    if ( _URC_FOREIGN_EXCEPTION_CAUGHT != code) {
        std::terminate();
    }
    delete exc;
}

public:
foreign_unwind_ex() noexcept {
    __GXX_INIT_FIBER_EXCEPTION_CLASS( exception_class);
    exception_cleanup = fiber_unwind_cleanup;
}
};
```

---

1. The personality routine passed by a specific runtime serves as interface between system unwinding library and language specific exception handling (not only C++, GO and Java are also supported). It is always invoked via pointer (saved as a function pointer in `.eh_frame` for each stack frame).
2. As a consequence the C++ personality routine deals only with C++ exceptions; it does not need to know anything specific about unwinding done by an external agent such as fiber or pthreads cancellation.
template< typename Ctx >
_Unwind_Reason_Code fiber_unwind_stop(
  int version,
  _Unwind_Action actions,
  _Unwind_Exception_Class exc_class,
  _Unwind_Exception * exc,
  _Unwind_Context * context,
  void * param) {
  if (actions & _UA_END_OF_STACK) {
    _Unwind_DeleteException(exc);
    // end of stack: switch back to calling fiber
    Ctx{param}.resume();
    __builtin_unreachable();
  }
  return _URC_NO_REASON;
}

```c

transfer_t fiber_unwind(transfer_t t) {
  _Unwind_ForcedUnwind(new foreign_unwind_ex{}, fiber_unwind_stop<Ctx>, t.fctx);
  __builtin_unreachable();
}
```

fiber_unwind() is called by std::unwind_fiber() or ~fiber_context() and starts the stack unwinding. The foreign exception foreign_unwind_ex∗ is allocated and passed as parameter to the unwinding library. Function fiber_unwind_stop() transfers execution control to the calling fiber once the last stack frame has been unwound.

**non-catchable foreign exception** std::unwind_fiber() uses a non-C++ foreign exception to force stack unwinding. As stated in the *SYS V AMD64 ABI* standard: "A runtime is not allowed to catch an exception if the _UA_FORCE_UNWIND flag was passed to the personality routine." and "... since it is not possible to determine if a given catch clause will re-throw or not without executing it ...", the foreign exception must not be catchable by C++ try-catch blocks.

As a consequence, std::current_exception() can not return a std::exception_ptr pointing to a foreign exception.

In order to detect if stack unwinding is currently in progress std::uncaught_exception() returns true and std::uncaught_exceptions() counts the foreign exception.

The rationale for moving to an uncatchable exception is further explained in the Revision History.

The specific characteristics of a foreign exception:

- Throwing the foreign exception can only be effected by the std::fiber_context facility. The proposed std::unwind_fiber() function is the only way to cause that explicitly.
- The ultimate “catch” – the point at which stack unwinding stops – is likewise determined by the std::fiber_context facility. There is no explicit syntax for this.
- Along the way, as with a normal C++ exception, every object in every stack frame is destroyed.
- catch clauses along the way are ignored.

The system’s exception handling, i.e. its unwinding framework, is used to clean up the stack of a fiber by using a foreign exception that is not catchable by C++ try-catch blocks.

Since unwinding a fiber’s stack requires destroying objects declared in stack frames, it is worth pointing out that destroying a non-empty std::fiber_context on a thread other than the thread on which it was last resumed will run those object destructors on the thread destroying the std::fiber_context instance.

As a consequence, destroying a std::fiber_context instance representing a thread’s default fiber (see Explicit Fiber vs. Implicit Fiber) from any other thread engages Undefined Behavior.†

*setting member variable makes foreign_unwind_ex a foreign exception
†One unobvious case would be if a fiber running on non-main() thread T stores a std::fiber_context representing T’s default
The \texttt{std::fiber_context} facility behaves as if there is an implicit top-level function above each explicit fiber's entry-function. (See Explicit Fiber vs. Implicit Fiber) This top-level function serves to delimit stack unwinding. Once the stack has been unwound to that point, it is as if control returns to the implicit top-level function. The implicit top-level function is conceptually responsible for freeing the explicit fiber's stack memory and for resuming the \texttt{std::fiber_context} designated as the next fiber.

**destroying a \texttt{std::fiber_context} representing a thread's default fiber**  
Similarly, the C++ runtime behaves as if there is a stack marker at or above \texttt{main()} (and each explicitly-launched thread's entry-function) that serves to delimit stack unwinding due to the foreign exception. Unlike an explicit fiber's top-level function, though, the conceptual top-level function on a thread's default fiber does not deallocate that fiber's stack: the OS, which provided the stack in the first place, will do that.

Unwinding the stack belonging to a thread's default fiber leaves the stack allocated but unreachable. That thread may continue to execute explicit fibers as long as desired.

Ultimately, however, it must be possible to exit a fiber in such as way as to terminate the calling thread. Returning an empty \texttt{std::fiber_context} instance from a fiber's entry-function terminates the running thread. Consequently, passing an empty \texttt{std::fiber_context} instance to \texttt{std::unwind_fiber()} also terminates the calling thread.

The \texttt{std::fiber_context} facility does not defend against the case in which a thread's default fiber suspends (rather than terminating), but the explicit fiber it resumes ultimately causes thread termination in either of the ways described above. A higher-level library built on \texttt{std::fiber_context} can provide a scheduler. The \texttt{std::fiber_context} facility intentionally does not.

The conceptual top-level function above \texttt{main()}, given an empty \texttt{std::fiber_context} instance to resume, terminates the whole process instead of that one thread.

**exceptions**

In general, if an uncaught exception escapes from a fiber's entry-function, \texttt{std::terminate} is called. There is one exception: the foreign exception used to unwind fiber stacks. The \texttt{std::fiber_context} facility internally uses this foreign exception to clean up the stack of a suspended fiber being destroyed. Because this exception is a foreign exception, it can not be caught.

**\texttt{std::fiber_context} as building block for higher-level frameworks**

A low-level API enables a rich set of higher-level frameworks that provide specific syntaxes/semantics suitable for specific domains. As an example, the following frameworks are based on the low-level fiber switching API of Boost.Context\cite{boost-context} (which implements the API proposed here).

**Boost.Coroutine2\cite{boost-coroutine2}** implements asymmetric coroutines coroutines' \texttt{push_type} and \texttt{pull_type}, providing a unidirectional transfer of data. These stackful coroutines are only used in pairs. When \texttt{coroutine<>::push_type} is explicitly instantiated, \texttt{coroutine<>::pull_type} is synthesized and passed as parameter into the coroutine function. In the example below, \texttt{coroutine<>::push_type (variable writer)} provides the resume operation, while \texttt{coroutine<>::pull_type (variable in)} represents the suspend operation. Inside the lambda, \texttt{in.get()} pulls strings provided by \texttt{coroutine<>::push_type}'s output iterator support.

```cpp
struct FinalEOL{ ~FinalEOL(){ std::cout << std::endl; } }
std::vector<std::string> words{ 
    "peas", "porridge", "hot", "peas",
    "porridge", "cold", "peas", "porridge",
    "in", "the", "pot", "nine",
    "days", "old" }
int num=5, width=15;
boost::coroutines2::coroutine<std::string>::push_type writer{
    &}(boost::coroutines2::coroutine<std::string>::pull_type& in){
    FinalEOL eol;
    for (; ){}
```

fiber in a static variable, whether module-scope or function-scope. That variable will be destroyed at program termination, probably on a thread other than T.
```cpp
for (int i=0; i<num; ++i){
    if (!in){
        return;
    }
    std::cout << std::setw(width) << in.get();
    in();
}
std::cout << std::endl;
```

```
std::copy(std::begin(words), std::end(words), std::begin(writer));
```

**Synca** by Grigory Demchenko) is a small, efficient library to perform asynchronous operations in synchronous manner. The main features are a **GO-like** syntax, support for transferring execution context explicitly between different thread pools or schedulers (portals/teleports) and asynchronous network support.

```cpp
int fibo(int v){
    if (v<2) return v;
    int v1,v2;
    Waiter()
        .go([v,&v1]{ v1=fibo(v-1); })
        .go([v,&v2]{ v2=fibo(v-2); })
        .wait();
    return v1+v2;
}
```

The code itself looks like synchronous invocations while internally it uses asynchronous scheduling.

**Boost.Fiber** implements **user-land threads** and combines fibers with schedulers (the scheduler algorithm is a customization point). The API is modeled after the **std::thread** API and contains objects such as **future**, **mutex**, **condition_variable**...

```cpp
boost::fibers::unbuffered_channel<unsigned int> chan;
boost::fibers::fiber f1{[&chan]{
    chan.push(1);
    chan.push(1);
    chan.push(2);
    chan.push(3);
    chan.push(5);
    chan.push(8);
    chan.push(12);
    chan.close();
}};
boost::fibers::fiber f2{[&chan]{
    for (unsigned int value: chan) {
        std::cout << value << " ";
    }
}]
    std::cout << std::endl;
};
f1.join();
f2.join();
```

**Facebook's folly::fibers** is an asynchronous C++ framework using **user-land threads** for parallelism. In contrast to **Boost.Fiber**, **folly::fibers** exposes the scheduler and permits integration with various event dispatching libraries.

```cpp
folly::EventBase ev_base;
auto& fiber_manager=folly::fibers::getFiberManager(ev_base);
folly::fibers::Baton baton;
fiber_manager.addTask([&]{
```
std::cout << "task 1: start" << std::endl;
baton.wait();
std::cout << "task 1: after baton.wait()" << std::endl;
}

fiber_manager.addTask([&]{
  std::cout << "task 2: start" << std::endl;
baton.post();
std::cout << "task 2: after baton.post()" << std::endl;
});

ev_base.loop();

_folly::fibers_ is used in many critical applications at Facebook for instance in _mcrouter_ and some other Facebook services/libraries like ServiceRouter (routing framework for _Thrift_), Node API (graph ORM API for graph databases) ... 

_Bloomber's _quantum_ is a full-featured and powerful C++ framework that allows users to dispatch units of work (a.k.a. tasks) as coroutines and execute them concurrently using the 'reactor' pattern. Its main features are support for streaming futures which allows faster processing of large data sets, task prioritization, fast pre-allocated memory pools and parallel forEach and mapReduce functions.

// Define a coroutine
int getDummyValue(Bloomberg::quantum::CoroContext<int>::Ptr ctx) {
    int value;
    ... //do some work
    ctx->yield(); //be nice and let other coroutines run (optional cooperation)
    ... //do more work and calculate 'value'
    return ctx->set(value);
}

// Create a dispatcher
Bloomberg::quantum::Dispatcher dispatcher;
// Dispatch a work item to do some work and return a value
int result = dispatcher.post(getDummyValue)->get();

_quantum_ is used in large projects at Bloomberg.

_Habanero Extreme Scale Software Research Project_ provides a task-based parallel programming model via its _HClib_. The runtime provides work-stealing, async-finish, parallel-for and future-promise parallel programming patterns. The library is not an exascale programming system itself, but it manages intra-node resources and schedules components within an exascale programming system.

As shown in this section a low-level API can act as building block for a rich set of high-level frameworks designed for specific application domains that require different aspects of design, semantics and syntax.

**interaction with STL algorithms**

In the following example STL algorithm _std::generator_ and _fiber g_ generate a sequence of Fibonacci numbers and store them into _std::vector v_.

```cpp
int a;
std::fiber_context g{[&a](std::fiber_context&& m) {
    a=0;
    int b=1;
    for(;;){
        m=std::move(m).resume();
        int next=a+b;
        a=b;
    }

```
possible implementation strategies

This proposal does NOT seek to standardize any particular implementation or impose any specific calling convention!

Modern micro-processors are register machines; the content of processor registers represents the execution context of the program at a given point in time.

Operating systems maintain for each process all relevant data (execution context, other hardware registers etc.) in the process table. The operating system’s CPU scheduler periodically suspends and resumes processes in order to share CPU time between multiple processes. When a process is suspended, its execution context (processor registers, instruction pointer, stack pointer, …) is stored in the associated process table entry. On resumption, the CPU scheduler loads the execution context into the CPU and the process continues execution.

The CPU scheduler does a full context switch. Besides preserving the execution context (complete CPU state), the cache must be invalidated and the memory map modified.

A kernel-level context switch is several orders of magnitude slower than a context switch at user-level.6

hypothetical fiber preserving complete CPU state This strategy tries to preserve the complete CPU state, e.g. all CPU registers. This requires that the implementation identifies the concrete micro-processor type and supported processor features. For instance the x86-architecture has several flavours of extensions such as MMX, SSE1-4, AVX1-2, AVX-512.

Depending on the detected processor features, implementations of certain functionality must be switched on or off. The CPU scheduler in the operating system uses such information for context switching between processes.

A fiber implementation using this strategy requires such a detection mechanism too (equivalent to swapper/system_32() in the Linux kernel).

Aside from the complexity of such detection mechanisms, preserving the complete CPU state for each fiber switch is expensive.

A context switch facility that preserves the complete CPU state like an operating system is possible but impractical for user-land.

fiber switch using the calling convention For std::fiber_context, not all registers need be preserved because the context switch is effected by a visible function call. It need not be completely transparent like an operating-system context switch; it only needs to be as transparent as a call to any other function. The calling convention – the part of the
ABI that specifies how a function’s arguments and return values are passed – determines which subset of micro-processor registers must be preserved by the called subroutine.

The calling convention\(^7\) of SYSV ABI for x86_64 architecture determines that general purpose registers R12, R13, R14, R15, RBX and RBP must be preserved by the sub-routine - the first arguments are passed to functions via RDI, RSI, RDX, RCX, R8 and R9 and return values are stored in RAX, RDX.

So on that platform, the `resume()` implementation preserves the general purpose registers (R12-R15, RBX and RBP) specified by the calling convention. In addition, the stack pointer and instruction pointer are preserved and exchanged too – thus, from the point of view of calling code, `resume()` behaves like an ordinary function call.

In other words, `resume()` acts on the level of a simple function invocation – with the same performance characteristics (in terms of CPU cycles).

This technique is used in `Boost.Context\(^8\)` which acts as building block for (e.g.) `folly::fibers` and `quantum`; see section `std::fiber_context` as building block for higher-level frameworks.

**in-place substitution at compile time** During code generation, a compiler-based implementation could inject the assembler code responsible for the fiber switch directly into each function that calls `resume()`. That would save an extra indirection (JMP + PUSH/MOV of certain registers used to invoke `resume()`).

**CPU state at the stack** Because each fiber must preserve CPU registers at suspension and load those registers at resumption, some storage is required.

Instead of allocating extra memory for each fiber, an implementation can use the stack by simply advancing the stack pointer at suspension and pushing the CPU registers (CPU state) onto the stack owned by the suspending fiber. When the fiber is resumed, the values are popped from the stack and loaded into the appropriate registers.

This strategy works because only a running fiber creates new stack frames (moving the stack pointer). While a fiber is suspended, it is safe to keep the CPU state on its stack.

Using the stack as storage for the CPU state has the additional advantage that `std::fiber_context` must only contain a pointer to the stack location: its memory footprint can be that of a pointer.

Section synthesizing the suspended fiber describes how global variables are avoided by synthesizing a `std::fiber_context` from the active fiber (execution context) and passing this synthesized `std::fiber_context` (representing the now-suspended fiber) into the resumed fiber. Using the stack as storage makes this mechanism very easy to implement.\(^*\) Inside `resume()` the code pushes the relevant CPU registers onto the stack, and from the resulting stack address creates a new `std::fiber_context`. This instance is then passed (or returned) into the resumed fiber (see synthesizing the suspended fiber).

Using the active fiber’s stack as storage for the CPU state is efficient because no additional allocations or deallocations are required.

**fiber switch on architectures with register window**

The implementation of fiber switch is possible – many libc implementations still provide the ucontext-API (`swapcontext()` and related functions)\(^†\) for architectures using a register window (such as SPARC). The implementation of `swapcontext()` could be used as blueprint for a fiber implementation.

**how fast is a fiber switch**

A fiber switch takes 11 CPU cycles on a x86_64-Linux system\(^‡\) using an implementation based on the strategy described in fiber switch using the calling convention (implemented in `Boost.Context`,\(^8\) branch `fiber`).

\(^*\)The implementation of `Boost.Context`\(^8\) utilizes this technique.

\(^†\)ucontext was removed from POSIX standard by POSIX.1-2008

\(^‡\)Intel XEON E5 2620v4 2.2GHz
interaction with accelerators

For many core devices several programming models, such as OpenACC, CUDA, OpenCL etc., have been developed targeting host-directed execution using an attached or integrated accelerator. The CPU executes the main program while controlling the activity of the accelerator. Accelerator devices typically provide capabilities for efficient vector processing\(^\ast\). Usually the host-directed execution uses computation offloading that permits executing computationally intensive work on a separate device (accelerator).\(^1\)

For instance CUDA devices use a command buffer to establish communication between host and device. The host puts commands (op-codes) into the command buffer and the device processes them asynchronously.\(^2\)

It is obvious that a fiber switch does not interact with host-directed device-offloading. A fiber switch works like a function call (see fiber switch using the calling convention).

multi-threading environment

Member function \texttt{can_resume\_from\_this\_thread()} returns \texttt{false} if the stack represented by the \texttt{std::fiber\_context} instance was created by the operating system (main application or thread stack), and the caller is running on a different thread. When the stack represented by the \texttt{std::fiber\_context} instance was created by \texttt{std::fiber\_context}'s constructor, \texttt{can_resume\_from\_this\_thread()} returns \texttt{true}.\(^3\) You must not attempt to resume an instance representing a stack provided by the operating system on some other thread!

\texttt{can_resume()} can be called to determine whether a given \texttt{std::fiber\_context} instance might safely be resumed on a particular thread by calling \texttt{resume()} or \texttt{resume\_with()}.

\texttt{std::fiber\_context} is TLS-agnostic - best practices related to TLS apply to fibers too (see P0772R0.)

There could potentially be Undefined Behavior if:

- code running on a fiber references thread local variables
- the compiler/runtime implementation caches a pointer to thread local storage on the stack
- that fiber is suspended, and
- the suspended fiber is resumed on a different thread.

The cached TLS pointer is now pointing to storage belonging to some other thread. If the original thread terminates before the new thread, the cached TLS pointer is now dangling.

For a runtime that caches TLS pointers in such fashion, an implementation of \texttt{resume\_from\_any\_thread()} or \texttt{resume\_from\_any\_thread\_with()} could conceivably walk the suspended stack, patching cached pointers.

acknowledgments

\(^\ast\)warp on CUDA devices, wavefront on AMD GPUs, 512-bit SIMD on Intel Xeon Phi

\(^1\)A possible implementation could mark the first stack frame by creating a special marker (for instance 0xBADCAFFE etc.) at a specific offset in the first stack frame or use a special function name for the first function and walk the stack searching for these markers.
33.7 Cooperative User-Mode Threads

33.7.1 General

The extensions proposed here support creation and activation of cooperative user-mode threads, here called fibers.

The term “user-mode” means that a given fiber can be activated without entering the operating-system kernel.

The term “cooperative” means that typically multiple fibers share an underlying execution agent, for example a `std::thread`.

On a given `std::thread`, only one fiber is running at any given time. Sharing that agent is explicit rather than pre-emptive.

The running fiber suspends (or yields) to another fiber. This action launches a new fiber, or resumes a previously-suspended fiber.

Suspending the running fiber in order to resume (or launch) another is called context switching.

The term “thread” in “cooperative user-mode thread” means that even though a given fiber may suspend and later be resumed, it is logically a thread of execution as defined in [intro.multithread].

Launching a fiber logically creates a new function stack, which remains associated with that fiber throughout its lifetime.

Calling functions on a particular fiber, and returning from them, is independent of function calls and returns on any other fiber.

Context switching can be effected by designating some other fiber’s stack as current, in a manner appropriate to the existing implementation of function stacks.

33.7.2 Empty vs. Non-Empty

A `std::fiber_context` instance may be empty or non-empty. A default-constructed `std::fiber_context` is empty.

A moved-from `std::fiber_context` is empty. A `std::fiber_context` representing a suspended fiber is non-empty.

33.7.3 Explicit Fiber vs. Implicit Fiber

It is convenient to take the position that every kernel thread in a program, including the default thread on which the program runs `main()`, has an initial default fiber whose stack is allocated by the host operating system. [Note: Thus, when `main()` instantiates a new `std::fiber_context`, it becomes the second fiber on that thread. —end note]

Upon resumption of a fiber, a non-empty `std::fiber_context` instance is passed in representing the newly-suspended previous fiber. This `std::fiber_context` instance might represent the thread’s default fiber, or it might represent an explicitly-launched fiber: a fiber explicitly instantiated by invoking `std::fiber_context`’s constructor.

In certain situations it is important to distinguish these two cases. In particular, it is Undefined Behavior to attempt to resume a thread’s default fiber on some other thread. We use the phrase explicit fiber or explicitly-launched fiber to designate a fiber instantiated by user code; conversely, implicit fiber designates the default fiber on any thread. An implicit fiber’s owning thread is the thread of which that fiber is the default fiber. An explicit fiber has no owning thread. Instead, when necessary, we speak of the thread on which a fiber was last resumed.

33.7.4 Implicit Top-Level Function

On every explicit fiber, the behavior is equivalent to injecting an implicit top-level stack frame above the `entry-function` passed to `std::fiber_context`’s constructor. If the fiber is later unwound, this conceptual top-level stack frame serves as delimiter: this point is where unwinding stops.

The conceptual top-level function must catch any C++ exception escaping from the fiber’s `entry-function` and call `std::terminate`.

Returning a `std::fiber_context` instance from the explicit fiber’s `entry-function` is equivalent to returning control to the implicit top-level function. Similarly, when `std::unwind_fiber()` unwinds a fiber stack, it conceptually returns the `std::fiber_context` instance it was passed to the implicit top-level function. Either way, the conceptual implicit top-level function is responsible for deallocating the explicit fiber’s stack memory.
Similarly, on every implicit fiber, the behavior is equivalent to passing control through an implicit top-level function above \texttt{main()} and above the \textit{entry-function} for each \texttt{std::thread}. The conceptual stack frame for this implicit top-level function delimits stack unwinding for each of these stacks. If the fiber stack is unwound, control is conceptually returned to this implicit top-level function. The conceptual top-level function for an implicit fiber does not deallocate the fiber’s stack memory, since the OS will do that.

- If a non-empty \texttt{std::fiber_context} instance is returned to the conceptual top-level function (for either an explicit or implicit fiber), the fiber represented by that \texttt{std::fiber_context} instance is resumed.
- If an empty \texttt{std::fiber_context} instance is returned to the conceptual top-level function for an explicit fiber, the calling thread is terminated.
- If an empty \texttt{std::fiber_context} instance is returned to the conceptual top-level function for the default fiber of an explicit thread, that thread is terminated.
- If an empty \texttt{std::fiber_context} instance is returned to the conceptual top-level function above \texttt{main()}, the process is terminated.

### 33.7.5 Header \texttt{<experimental/fiber_context>} synopsis

```cpp
#include <fiber_context>
#define __cpp_lib_experimental_fiber_context 201907
namespace std {
    namespace experimental {
        inline namespace concurrency_v2 {
            class fiber_context;
            class unwind_exception;
            void unwind_fiber(fiber_context&& other);
        } // namespace concurrency_v2
    } // namespace experimental
} // namespace std
```

### 33.7.6 Class fiber_context

```cpp
namespace std {
    namespace experimental {
        inline namespace concurrency_v2 {
            class fiber_context {
                public:
                    fiber_context() noexcept;
                    template<typename Fn>
                    explicit fiber_context(Fn&& fn);
                    ~fiber_context();
                    fiber_context(fiber_context&& other) noexcept;
                    fiber_context& operator=(fiber_context&& other) noexcept;
                    fiber_context(const fiber_context& other) noexcept = delete;
                    fiber_context& operator=(const fiber_context& other) noexcept = delete;
                    fiber_context resume() &&;
                    template<typename Fn>
                    fiber_context resume_with(Fn&& fn) &&;
                    fiber_context resume_from_any_thread() &&;
                }
            }
        }
    }
}
template<typename Fn>
fiber_context resume_from_any_thread_with(Fn&& fn) &&;

bool can_resume() noexcept;
bool can_resume_from_any_thread() noexcept;

explicit operator bool() const noexcept;
bool valid() const noexcept;
void swap(fiber_context& other) noexcept;
};

} // namespace concurrency_v2
} // namespace experimental
} // namespace std

(constructor) constructs new fiber_context

fiber_context() noexcept

template<typename Fn>
explicit fiber_context(Fn&& fn)

fiber_context(fiber_context&& other) noexcept

fiber_context(const fiber_context& other)=delete

1) this constructor instantiates an empty std::fiber_context. Its empty() method returns true.

2) takes a invocable object [func.def] as argument. The invocable must have signature fiber_context fn(fiber_context&&).
   This constructor template shall not participate in overload resolution unless Fn is Lvalue-Invocable [func.wrap.func]
   for the argument type std::fiber_context&& and the return type std::fiber_context.
   SG1: Needs update to Invocable idiom.

3) moves underlying state to new std::fiber_context

4) copy constructor deleted

Remarks:

— The entry-function fn is not immediately entered.
  The stack and any other necessary resources are created on construction, but fn is entered only when resume(),
  resume_with(), resume_from_any_thread() or resume_from_any_thread_with() is called.

— A newly constructed but not yet entered fiber may be resumed by any thread. For any explicit fiber, the thread that
  resumes it is constrained only by the last thread that previously resumed it – and that constraint is imposed by
  operations performed by the fiber, rather than by the std::fiber_context facility itself.

— The entry-function fn passed to std::fiber_context will be passed a synthesized std::fiber_context instance
  representing the suspended caller of resume(), resume_with(), resume_from_any_thread() or
  resume_from_any_thread_with().

~fiber_context ()

Effects:

— destroys a std::fiber_context instance. If this instance represents a fiber of execution (empty() returns false),
  then the fiber of execution is destroyed too.

Remarks:

— Destroying a suspended fiber causes its stack to be unwound – equivalent to calling
  resume_from_any_thread_with(unwind_fiber).

— The destructors of the stack variables on the suspended fiber represented by *this are run on the thread calling
  ~fiber_context().

— As a consequence, destroying a std::fiber_context instance representing an implicit fiber from some other thread
  engages Undefined Behavior.
operator= moves the std::fiber_context object

```cpp
fiber_context& operator=(fiber_context&& other) noexcept (1)
fiber_context& operator=(const fiber_context& other)=delete (2)
```

Effects:
1) assigns the state of other to *this using move semantics
2) copy assignment operator deleted

Parameters:
other another std::fiber_context to assign to this object

Returns:
*this

Postconditions:
other is made empty (empty() returns true)

resume() resumes a fiber

```cpp
template<typename Fn>
fiber_context resume_from_any_thread_with(Fn&& fn) &&
```

Requires:
- *this represents a non-empty fiber (empty() returns false)
- can_resume_from_this_thread() would return true

Effects:
- This member function template shall not participate in overload resolution unless Fn is Lvalue-Invocable [func.wrap.func] for the argument type std::fiber_context&& and the return type std::fiber_context.
  SG1: Needs update to Invocable idiom.
- The execution context of the calling fiber is saved.
- The calling fiber is suspended.
- A new std::fiber_context instance representing the suspended caller is synthesized. For purposes of exposition, call it caller.
- The fiber represented by *this is resumed.
- The execution context of the resumed fiber is restored.
- The invocable fn is called on the newly-resumed fiber.
- caller is passed to fn.
- If fn throws an exception, the exception propagates on the newly-resumed fiber.
- Otherwise fn eventually returns a std::fiber_context instance. For purposes of exposition, call it returned.
  [Note: returned may or may not be the same as caller. — end note] [Note: returned may be empty. — end note]
- If this is the first entry to the fiber represented by *this, returned is passed to its entry-function.
- Otherwise, the fiber represented by *this previously suspended itself by calling one of resume(), resume_with(), resume_from_any_thread() or resume_from_any_thread_with(). returned is returned from whichever of the resume functions was called.

Parameters:
fn invocable object injected into resumed fiber

Returns:
**fiber_context** on resumption, `resume_from_any_thread_with()` returns a `std::fiber_context` representing the immediately preceding fiber: the fiber that resumed this one, thereby suspending itself.

**Exceptions:**

— `resume_from_any_thread_with()` can throw any exception if, while suspended:
  
  - some other fiber calls `resume_with()` or `resume_from_any_thread_with()` to resume this suspended fiber, and
  
  - the function `fn` passed to `resume_with()` or `resume_from_any_thread_with()` – or some function called by `fn` – throws an exception

— Any exception thrown by the function `fn` passed to `resume_from_any_thread_with()`, or any function called by `fn`, is thrown in the fiber referenced by `*this` rather than in the fiber of the caller of `resume_from_any_thread_with()`.

**Postconditions:**

— `*this` is made empty (`empty()` returns `true`)

[Note: The intent of the names `resume_from_any_thread()` and `resume_from_any_thread_with()` is to clarify the direction in which cross-thread resumption occurs. The calling thread always directly resumes a suspended fiber: control is passed into the suspended fiber, and the currently-running fiber suspends. These method names mean that the fiber represented by `*this` will be resumed whether or not it was last resumed on the calling thread. — end note]

[Note: A suspended `fiber_context` can be destroyed. Its resources will be cleaned up at that time. — end note]

[Note: The returned `fiber_context` indicates via `empty()` whether the previous active fiber has terminated (returned from `entry-function`). — end note]

[Note: Because `resume()`, `resume_with()`, `resume_from_any_thread()` or `resume_from_any_thread_with()` empties the instance on which it is called, no non-empty `std::fiber_context` instance ever represents the currently-running fiber. In order to express the state change explicitly, these methods are rvalue-reference qualified. — end note]

[Note: When calling any of these methods, it is conventional to replace the newly-emptied instance – the instance on which the method was was called – with the new instance returned by that call. This helps to avoid subsequent inadvertent attempts to resume the old, empty instance. — end note]

```cpp
template<typename Fn>
fiber_context resume_with(Fn&& fn) &&
```

[Note: The intent of the distinction between `resume()` and `resume_from_any_thread()`, as between `resume_with()` and `resume_from_any_thread_with()`, is both for validation and for code auditing. If an application only ever calls `resume()` or `resume_with()`, no fiber in that application will ever be resumed on a thread other than the one on which it was previously resumed. — end note]

**Requires:**

— `*this` represents a non-empty fiber (`empty()` returns `false`)

— the calling thread is the same as the thread on which the fiber represented by `*this` was most recently resumed

**Effects:**

— `resume_with()` has the same semantics as `resume_from_any_thread_with()`.

— In addition, `resume_with()` may validate that the calling thread is the same as the thread on which the fiber represented by `*this` was most recently resumed.

```cpp
fiber_context resume_from_any_thread() &&
```

**Effects:** Equivalent to:

```cpp
resume_from_any_thread_with([](fiber_context&& caller){ return caller; })
```

```cpp
fiber_context resume() &&
```

**Effects:** Equivalent to:

```cpp
resume_with([](fiber_context&& caller){ return caller; })
```

```cpp
bool can_resume_from_this_thread() noexcept
```
Effects: query whether the calling thread can resume the suspended
std::fiber_context instance by calling resume_from_any_thread() or resume_from_any_thread_with().

Returns:
— fiber_context::can_resume_from_this_thread() returns false if *this is empty, or if it represents an
implicit fiber, and the calling thread is not that fiber’s owning thread; otherwise true.

Remarks:
— You may resume a suspended implicit fiber on the same thread using any of
resume(), resume_with(), resume_from_any_thread() or resume_from_any_thread_with(). Attempt-
ing to resume an implicit fiber from any thread other than its owning thread is Undefined Behavior.
— can_resume_from_this_thread() returns true if the calling thread is the same as the thread on which the fiber
represented by *this was most recently resumed, or if the std::fiber_context instance represents an explicit
fiber.
— can_resume_from_this_thread() is not marked const because in at least one implementation, it requires an
internal context switch. However, the stack operations are effectively read-only. Nonetheless, if it is possible
for more than one thread to call can_resume_from_this_thread() concurrently on the same non-empty
std::fiber_context instance, locking is the caller’s responsibility.

bool can_resume() noexcept
Returns: false if *this is empty, or if the calling thread is not the same as the thread on which the fiber represented by
*this was most recently resumed. [Note: When can_resume() returns true, the std::fiber_context instance may
be resumed by resume(), resume_with(), resume_from_any_thread() or resume_from_any_thread_with().
— end note]

Remarks:
— can_resume() is not marked const because in at least one implementation, it requires an internal context switch.
However, the stack operations are effectively read-only. Nonetheless, if it is possible for more than one thread to
call can_resume() concurrently on the same non-empty std::fiber_context instance, locking is the caller’s
responsibility.

empty() test whether std::fiber_context is empty

bool empty() const noexcept (1)

explicit operator bool() const noexcept (2)

Returns:
1) returns false if *this represents a fiber of execution, true otherwise.
2) equivalent to (! empty())

[Note: Regardless of the number of std::fiber_context declarations, exactly one
std::fiber_context instance represents each suspended fiber. — end note]

void swap(fiber_context& other) noexcept

Effects:
— Exchanges the state of *this with other.

33.7.7 Function unwind_fiber() [fiber-context.unwinding]

[[ noreturn ]] void unwind_fiber(fiber_context&& other)

Effects: terminate the current running fiber.

Remarks:
— The underlying Unwinding facility (for instance the unwind facility described in System V ABI for AMD64) unwinds
the stack to the implicit top-level stack frame and terminates the current fiber as described above.
— Unwinding the fiber’s stack causes its stack variables to be destroyed.
— During this specific stack unwinding, no `catch` clauses are executed, not even `catch (...)`.
— Once the running fiber has been fully unwound, `other` is returned to the fiber’s conceptual top-level function as described in Implicit Top-Level Function.

Parameters:

`other` the `std::fiber_context` to which to switch once the current fiber has terminated

Returns:

— None: `std::unwind_fiber()` does not return

Exceptions:

— None catchable by C++
